During the years under review the feeding of prisoners was investigated by Mr. MAGNUS PYKE, D SC. He found various deficiencies, chiefly in vitamins, which were afterwards largely corrected. He also found that the food supplied to borstal boys was inadequate in quantity, and this was overcome by a substantial increase in the bread-supply. In all prisons and borstals there was a shortage of fat in the diet, and dried eggs were excluded except for hospital use, which indicates that the commissioners estimate nutritional needs at a lower level than that set by ordinary rationing. While recording many small attempts to improve the lot of prisoners and give them an opportunity to develop into normal citizens, the report as a whole makes all too clear how much is still wrong with our attempts at criminal justice. Lord TEMPLEWOOD's Criminal Justice Bill of 1938, by raising the minimum age for imprisonment to 16, would have ensured that no young offender could be sent to prison by a court of summary jurisdiction; and none between 17 and 21 unless he could not safely be detained in a remand home. Inside the prisons, as he pointed out in his lecture, work should not be lifeless, but useful, interesting, and reformative, though hard. He would like to see it modernised on the lines set out by the Salmon Committee, who considered that the system of earnings, which stimulates interest and self-respect, should be more widely developed. He shares our belief that mental abnormality should be taken into account in assessing criminal responsibility: the courts, he believes, should be able to order the mental examination of offenders put on probation, and those who need it should be treated at the public expense. Young offenders, if they are to be kept out of prison, might go to attendance centres once a week, and perhaps live in special hostels for a while, from which they could go out to work.

Yet he does not believe that even these much-needed reforms can cure our troubles; for our sickness is moral, and "however we may explain it, many moral restraints have lost much of their power in the confused and restless world of today." Civilised behaviour springs from mutual trust and personal integrity; we have to re-create a world in which these things are valued.

Sedimentation-rate

THE use of erythrocyte-sedimentation as a diagnostic aid originated some four hundred years B C. with the observation of HIPPOCRATES that sickness was accompanied by an increase in the phlegma or mucus, the uppermost of the blood's four humors. So constant was this change that the Greeks concluded that the phlegma was the most important cause of illness GALEN, in the 2nd century A D., persuaded Roman physicians to adopt this theory, which was accepted without serious question for the next 17

ANTUITRIN 'S'

(ANTROIDIN)

A standardized solution of chorionic gonadotrophin obtained from human pregnancy urine

In the female the effect of Antuitrin 'S' is mainly luteinizing, and it is indicated in functional uterine bleeding, dysmenorrhœa, amenorrhœa, oligomenorrhœa, and habitual and threatened abortion.

In the male Antuitrin 'S' acts on the interstitial cells of the testes, increasing secretion of the male hormone, and is used in the treatment of cryptorchidism, impotence, and aspermia.

In both sexes it has been shown to be valuable in delayed puberty, genital infantilism, acne vulgaris, adipose-genital dystrophy (Fröhlich's syndrome), and in some cases of sterility.

Packages

Antuitrin 'S' is supplied in rubber-capped vials of 10 c.c. (100 International units per c.c.) and 5 c.c., Concentrated Solution (500 International units per c.c.)

Justice and Prison

AMONG criminals, the young are the most easily reclaimed, and the most easily confirmed in crime. Lord TEMPLEWOOD, lecturing on Jan. 31 in the new department of criminal science in the law school at Cambridge,[1] affirmed that the fundamental problem of crime is juvenile delinquency; and he went on to discuss our disquieting failure to solve this problem. It is generally recognised that the numbers of young offenders increased during the late war—between 1938 and 1945 the offences committed by children and young people under twenty-one rose by more than half the rate of previous years—but it is less widely known that between 1907 and the beginning of the 1939 war the numbers of young offenders found guilty had already increased by 125%. We have now reached a point when 1 child in 90 between the ages of eleven and sixteen is found guilty of an indictable offence; and this figure takes no account of the many children not brought into court for their offences, or of the many offences not brought to the notice of the police. Our chosen reformative methods—probation, and training in approved schools—can give good results when properly applied; but in many places, Lord TEMPLEWOOD finds, probation is equated with dismissal or acquittal, cases are not properly followed up, and aftercare is scarcely attempted when the probationary period is over.

Nor are the approved schools and borstal institutions anything like satisfactory at present, as the latest report[2] of the Prison Commissioners and the Directors of Convict Prisons reveals. Admittedly they were working under great difficulties raised by the war: staff shortage, "war restrictions, blackout, and an increasing restlessness of youth." This last element—which in one light seems healthy evidence of independence and spirit—was responsible, the commissioners say, for an increase in absconding; but surely it means, too, that the schools and borstals were not offering these growing minds enough to hold them. Naturally the task is extremely difficult; the aim, the report says, is "to hold the balance between too tight a rein, which would inhibit personal development and frustrate the intention of the [Prevention of Crime] Act, and too loose a rein, which would equally be bad training and may make the Institution unwelcome to its neighbours." They add that in the years under review the hold on this purpose has been subject to considerable strain. Lack of staff and accommodation made it necessary to reduce the average period of training, and the amount of aftercare given had to be reduced. Despite these difficulties, over 4000 of the 6084 youths discharged between April, 1942, and March, 1945, entered the Services, and most of them did well, several becoming officers and many N.C.O.s. The training must therefore have been fitted to the needs of a large proportion of boys committed to approved schools and borstals; and with better staffing and quarters could no doubt give even better results. The care of girls has been disappointing: "It cannot be denied that the percentage of girls who have done well is low." Of 638 discharged between 1938 and 1942, 31·5% have already been convicted again on two or more occasions, and only half have avoided a reconviction. The girls under care may be a more hardened lot than the boys, but evidently there is room for advance in the management of institutions training them.

During the years under review the feeding of prisoners was investigated by Mr. MAGNUS PYKE, D.SC. He found various deficiencies, chiefly in vitamins, which were afterwards largely corrected. He also found that the food supplied to borstal boys was inadequate in quantity, and this was overcome by a substantial increase in the bread-supply. In all prisons and borstals there was a shortage of fat in the diet, and dried eggs were excluded except for hospital use, which indicates that the commissioners estimate nutritional needs at a lower level than that set by ordinary rationing. While recording many small attempts to improve the lot of prisoners and give them an opportunity to develop into normal citizens, the report as a whole makes all too clear how much is still wrong with our attempts at criminal justice. Lord TEMPLEWOOD's Criminal Justice Bill of 1938, by raising the minimum age for imprisonment to 16, would have ensured that no young offender could be sent to prison by a court of summary jurisdiction; and none between 17 and 21 unless he could not safely be detained in a remand home. Inside the prisons, as he pointed out in his lecture, work should not be lifeless, but useful, interesting, and reformative, though hard. He would like to see it modernised on the lines set out by the Salmon Committee, who considered that the system of earnings, which stimulates interest and self-respect, should be more widely developed. He shares our belief that mental abnormality should be taken into account in assessing criminal responsibility: the courts, he believes, should be able to order the mental examination of offenders put on probation, and those who need it should be treated at the public expense. Young offenders, if they are to be kept out of prison, might go to attendance centres once a week, and perhaps live in special hostels for a while, from which they could go out to work.

Yet he does not believe that even these much-needed reforms can cure our troubles; for our sickness is moral, and "however we may explain it, many moral restraints have lost much of their power in the confused and restless world of today." Civilised behaviour springs from mutual trust and personal integrity; we have to re-create a world in which these things are valued.

Sedimentation-rate

THE use of erythrocyte-sedimentation as a diagnostic aid originated some four hundred years B.C. with the observation of HIPPOCRATES that sickness was accompanied by an increase in the phlegma or mucus, the uppermost of the blood's four humors. So constant was this change that the Greeks concluded that the phlegma was the most important cause of illness. GALEN, in the 2nd century A.D., persuaded Roman physicians to adopt this theory, which was accepted without serious question for the next 17 centuries. From this faith sprang the ritual of blood-letting as a remedy and a guide to diagnosis and prognosis. Physicians of the 18th and early 19th centuries, when phlebotomy reached its peak of popularity, used to watch the sedimentation of blood standing in large brass bowls and vary the amount of blood removed accordingly. In the 1850's the humoral theory was overridden by VIRCHOW with his cellular pathology, and, while venesection fell from favour, research-workers found a field for exploration more fascinating than the naked-eye appearances of blood. In 1893 BIERNACKI returned to the study of blood-sedimentation, urging its importance in diagnosis, but his words fell on deaf ears. A further twenty years passed before FAHRAEUS,[1] in 1918, popularised the test. Since then it has been the subject of more papers, and of more controversy, than any other laboratory procedure. Physicians, surgeons, pathologists, and general practitioners all adhere to their favourite methods of estimating the sedimentation-rate; the multiplicity would matter little if results were comparable, but this, despite nomographs, they are not. If blood-sugar values were reported in as many ways as the sedimentation-rate, the confusion would endanger lives.

[2] Report for the years 1942–44. H.M. Stationery Office. Pp. 154. 2s. 6d

Among clinicians the Westergren technique holds first place; 1·6 c.cm. of venous blood is drawn into a syringe containing 0·4 c.cm. of a 3·8% solution of sodium citrate, and the mixture is set up in a 200 mm. graduated tube. The result is expressed as the fall of the erythrocyte column in one hour. It is an advantage of this method that dilution diminishes the sensitivity of the test by retarding the initial fall, so that the normal range after an hour's fall does not exceed 5 mm. for a man and 7 mm. for a woman or child; at the same time the fall is exaggerated in pathological bloods. A disadvantage is that the same blood sample cannot afterwards be used with reliability for other purposes. If, however, blood from a previously dry syringe is added to a narrow-bore tube containing the diluent, the tube having been previously marked at the 2 c.cm. level, the rest of the blood may be used for other tests and the patient will be spared a second puncture. This device is often frowned on, but it achieves equally great accuracy in dilution. Of late years, techniques employing undiluted blood have been favoured as more reliable than the Westergren method, though such criticism has often been based more on errors in performance than on any faults inherent in the test; the common mistakes are inaccurate dilution, inconstant temperature (high temperature increases the rate), initial delay in setting up the test, and failure to keep the tubes strictly vertical. With the Westergren technique the reading is not easily corrected for anæmia. In anæmic blood sedimentation is hastened, so the observed rate will be too high. This will not matter much when, for example, the progress of a case of tuberculosis is being watched, for improvement in the anæmia will usually go hand in hand with improvement in general condition. But in diagnosis, particularly that of rheumatic disease, the presence of anæmia may be seriously misleading, unless the reading is corrected against an estimation of hæmoglobin or packed-cell volume, or a red-cell count. With the Westergren technique one of these estimations must be done separately before a correction can be made. One of the reasons why pathologists on the whole favour the Wintrobe method is that being done in a hæmatocrit mere centrifugalisation will give the packed-cell volume, from which the sedimentation reading can easily be corrected from the published charts. Moreover, with the Wintrobe method, other procedures can be carried out on the same blood-sample, for the blood is not diluted, being kept fluid by the addition of heparin or HELLER and PAUL'S[2] mixture of ammonium and potassium oxalate, designed to prevent shrinkage of the erythrocytes. The Wintrobe test is set up in a 100 mm. graduated hæmatocrit tube held vertically and read at the end of an hour. There being no dilution to retard sedimentation, the range of normality is greater—up to 9 mm. for a man and 20 mm. for a woman or child—while owing to the shorter tube the scale of abnormality is reduced. In the wide-bore or "spa" method,[3] a highly sensitive modification of the Wintrobe technique, 5 c.cm. of oxalated blood is allowed to settle in a wide graduated centrifuge tube and the result is expressed as a percentage, sometimes of the plasma layer to the total volume and sometimes in terms of the cell-bulk. The wide tube makes a strictly vertical posture less essential, and it is easier to fill and to clean; the packed-cell volume can also be easily obtained by running the tube in the centrifuge. Many other techniques are in common use. One of the most popular is the micro-method, practised in many ways, which is designed to obviate venepuncture and is reliable provided the tube is wide enough to exclude the effect of surface tension.

To sum up. When the sedimentation-rate is used as a periodic test of progress, the method is immaterial, provided the same technique is always used, and the choice is based on convenience. Thus the Westergren is favoured for watching the course of pulmonary tuberculosis, while the wide-bore method is convenient for controlling treatment in rheumatoid arthritis, and a micro-technique for the review of rheumatic children. In these diseases the test is more than a check on clinical acumen, for an increased rate often presages relapse. For diagnosis the choice of method is more difficult. Westergren's is possibly best unless a more sensitive technique is required, as in a suspected case of rheumatoid arthritis, and where correction for anæmia is desirable when the Wintrobe or the wide-bore techniques are preferable. The correction against packed-cell volume often gives valuable help, for the hæmatocrit is an independent yardstick of progress in rheumatoid arthritis.[4] When all is said and done the sedimentation-rate remains simply an empirical test of clinical convenience. Factors influencing the rate are being slowly elucidated with improving analysis of plasma-proteins. Thus GORDON and WARDLEY[5] have separated these into 9 fractions, which they combine in 39 pairs; they find that fibrinogen and euglobulin are "fast" and are inhibited by the "slow" nucleoprotein and globoglycoid. They conclude that the rate of sedimentation is controlled not by the absolute concentration of the otal plasma-proteins or of the protein fractions but y the inhibition of one protein by another. A high ibrinogen content, for instance, may be found with low sedimentation-rate, owing to an increase of seudoglobulin at the expense of euglobulin, the total globulin remaining stationary. An increased sedimentation-rate, they say, normally denotes an alteration not in the chemical structure of the proteins (with the possible exception of Bence-Jones protein) but only in their relative proportions. It seems likely, therefore, that the test will ultimately disappear when electrophoretic analysis of proteins is generally adopted. Until then attempts to over-elaborate what is an essentially simple clinical test are to be discouraged.

The Serum of Bogomoletz

For the past fourteen years Russian pathologists, headed by the late Academician Alexander Bogomoletz, a pupil of Metchnikov's, have been studying the therapeutic properties of antireticular cytotoxic serum—A.C.S. for short. Knowledge of this work outside Russia has largely been founded on scientific gossip and a few odd snippets in the daily press, though Bogomoletz published short summaries[1] here and in America in 1943. His review stimulated American research-workers into action, and the first results of their inquiries are now coming through.

The Russians, according to Straus,[2] claim that A.C.S. in carefully graded doses is beneficial in fractures, murine typhus, schizophrenia, rheumatism, scarlet fever, hypertension in its early stages, tuberculosis, inoperable carcinoma, and frostbite. To these we may add reports in the popular press that it is good for the degenerative changes of old age. But A.C.S. is no old-fashioned panacea, for it was found to be without effect in erysipelas. Straus's review enables one to piece together the theoretical background of these extraordinary claims. In the first place, by "reticular" tissue Bogomoletz meant not merely the reticulo-endothelium but the whole of what many histologists call the "mesenchymal" tissue—the hæmopoietic tissues and their derivatives, vascular and lymphatic endothelium, and all the cells belonging to the superfamily of fibroblasts. If human spleen or bone-marrow extracts (both wholly mesenchymal) are injected into horses, rabbits, or goats, tissue-specific antibodies are formed which in high concentration are toxic to cells of the type that called them forth. But in low concentration, as determined by a standard complement-fixation test, the action of the antibodies is stimulatory—an idea first suggested by Metchnikov himself. It is to the generalised stimulating effect of A.C.S. in low dosage that its beneficent properties are ascribed.

There is nothing particularly novel or surprising in the idea that tissue-specific antibodies may be elicited by injecting cells into an animal of another species.[3] Indeed, Cruickshank's[4] work on antilymphocytic sera suggests that antibodies may be aimed more exactly than against the mesenchymal tissues as a whole. For many years, moreover, workers on tissue culture have claimed that such tissue-specific antisera have a toxic action in vitro. Pomerat and Anigstein[5] have investigated the properties of A.C.S. itself by tissue-culture methods; and in confirming its cytotoxic action they find that a high degree of species-specificity is superimposed on its specificity towards mesenchymal tissues, in the sense that anti-rat-spleen antibodies will inhibit the growth of a rat sarcoma in culture, where an anti-chicken-spleen serum will not. So far so good; but the novelty and the whole theoretical substance of Bogomoletz's claims turn on whether such antisera are stimulating in low dosages. It is technically very difficult to demonstrate feeble stimulatory actions by tissue-culture methods, but in preliminary work Pomerat[6] does indeed find that the outwandering of cells from chick-heart fragments is stimulated by homologous (i.e., anti-chick) A.C.S. in low dosages.

No clinician, of course, will be satisfied with anything less than a clean-cut demonstration of the effectiveness of A.C.S. in vivo, and here (after satisfying themselves with the validity of their technique of assay and other technical details) Straus and his colleagues[7] have made a beginning. They chose in particular to study the most overtly reasonable claim—that A.C.S. in the appropriate low dosages expedites the healing of fractured bones. The A.C.S. was prepared by injecting rabbit spleen and bone-marrow extracts into goats, and its titre adjusted by complement-fixation to 1 : 130. Rabbits were now subjected to a standard complete fracture of the radius and ulna in a modified Grattan osteoclast and divided for injections into four groups. Each rabbit in the first group received a "stimulating" dose of 0·00125 ml. and each in the second group the inhibitory dose of 0·10 ml. Members of the third and fourth groups received 0·00125 ml. and 0·10 ml. of normal goat serum. After two weeks the efficiency of healing was determined by radiography, histological examination, and measurement of the breaking strength of the union. All three methods combined to affirm that the 0·1 ml. dose of A.C.S. has a depressive action on healing. The mechanical method alone gave evidence that the fractures healed better in the rabbits that received the stimulating dose of A.C.S. than in the controls; whereas the breaking strengths of the bones in the stimulated groups were clustered more or less symmetrically round a mean value of 6·83 kg., the results from about a third of the controls were clustered around zero, though the other readings had about the same range of scatter as the experimental set. In short, a shot has been fired for the defence; and editorial and private comment on A.C.S., which has hitherto been cool, may be warmer after this discovery. Since A.C.S. keeps well and is not difficult to prepare (though the source of antigen may give trouble), it is to be hoped that equally critical trials will be made of the other benefactions alleged to be within its gift. So far, supplies have permitted only one small trial in England—that of Bach[8] for the Empire Rheumatism Council—and its results were unfavourable.

Annotations

NEGOTIATION

LAST week the Royal College of Physicians of London expressed its wish that the Negotiating Committee, on which it has three representatives, should "enter into discussions and negotiations with the Minister on the regulations authorised by the National Health Service Act." Neither this resolution nor the similar ones passed by the councils of the two other English Royal Colleges lays down conditions on which negotiations will be resumed: unlike the resolution passed on Jan. 28 by the representative body of the British Medical Association they do not refer to the possibility of amending legislation. On the other hand they by no means commit the colleges to approval of any part of the Government's scheme which after negotiation appears unacceptable to the profession. Opinions have differed and still differ on several sections of the Act, and the representatives of different bodies will no doubt look at it from different angles; but their general unity will be preserved so long as they are all trying to produce, by agreement, a workable service. This is also the desire of the Ministry, and we believe that joint effort will in the end prove capable of removing both mountains and molehills.

SURGERY IN VESICOVAGINAL FISTULA

THE surgeon planning his line of treatment for a case of carcinoma of the urinary bladder—one of the most distressing of human ailments—is not likely to be swayed by the mortality and end-results of ureterocolostomy. Excision of the malignant bladder after diversion of the urine into the colon or on to the skin offers the only chance of cure, even if the operative mortality is about 50% and few patients survive for longer than five years. The fate of untreated cases is so hopeless and their end so terrible that the surgeon may with justice ignore, while striving to diminish, the enormous operative mortality. But the problem is very different in the patient with a non-malignant vesicovaginal fistula. In this condition the operation of ureterocolostomy ignores the primary pathology, which is neither progressive nor lethal, and deals with the symptom—the urinary leak. The operation neither saves nor prolongs life; in all probability life will be shortened. Local plastic repair of the fistula is to be preferred whenever possible, since thereby a return to normal micturition is obtained. Some surgeons, notably Mahfouz Pasha in Egypt, Hayes in India, and Chassar Moir in England, have had great experience of this difficult operation and have reported a high proportion of successes. But unless we know the severity of the original lesions, figures representing percentage successes can be very misleading. There are cases in which plastic repair has been so often unsuccessful even in expert hands that they must be considered irreparable. These are particularly common among primitive peoples where modern midwifery is unobtainable. The well-intentioned habit of some native tribes of packing the postpartum vagina with rock salt to promote fibrosis and shrinkage leads to a particularly intractable type of fistula after the next obstructed labour. In the West African series described by Lovett-Campbell on another page fibrosis and thickening of the bladder from chronic bilharziasis was a feature of the intractable cases.

In cases like these the relative merits of ureterocolostomy and conservative measures, such as the use of receptacles, inefficient as they are, must be considered. The patient is entitled to know the hazards and end-results of the operation in order to weigh them against the discomfort and misery of her condition. In the final analysis the patient, guided by an honest presentation of the facts by the surgeon, must herself make the decision. In average hands the operative mortality is in the region of 15%. Especially skilled operators have from time to time presented lower figures, but it is the average which must be sought while the best is aimed at. What of the end-results? Control of rectal micturition is the rule, though occasionally there is incontinence at night. As far as expectation of life is concerned, there is no doubt that a long and reasonably healthy life is possible after ureterocolostomy. Grey Turner[1] has recorded the histories of 9 patients, survivors of an original series of 17, who were alive sixteen to thirty years after operation. Wade[2] has published records of 16 patients, from an original group of 21 suffering from benign conditions, who were alive up to fourteen years after operation. Lower[3] reported on 6 patients who were living twenty years after operation. Of the late complications, there is evidence that about half the cases develop some form of renal disease. Thus 4 of Grey Turner's 9 patients had renal complications. Hydronephrosis, chronic infection, and nephrolithiasis are all known to occur. It is a tribute to nature's adaptability that these complications do not develop in all the patients. Conception and childbearing are not contra-indicated after the operation. One of Grey Turner's patients bore several children, and Lovett-Campbell mentions that 2 of his patients subsequently went through pregnancy and labour without mishap.

The facts, in summary, are these. The operative risk is high but not excessive, the expectation of life is fairly good, some renal impairment develops in half the cases, continence is almost certain, and pregnancy and labour are not impossible. In the face of this evidence who can doubt what is the right advice to give to the unfortunate woman who is inflicted with an intractable vesicovaginal fistula or what choice they themselves would make if they had the necessary training to grasp the facts?

INTELLIGENCE AND FERTILITY

WE hear a good deal these days of the potential menace to the nation of the present trends in reproduction-rates among the more intelligent section of the population.[1] In a discussion at the Eugenics Society on Jan. 21, Lord Horder, who was in the chair, said that intelligence, in so far as it can be measured by formal tests, is clearly a heritable function of the mind. A negative association has been observed between the intelligence-test scores and the size of the family to which the tested child belongs, which means that the more intelligent parents of the more gifted children in all social classes are tending to have small families. A continuation of present trends would reduce the proportion of children with high mental endowment and increase the frequency of feeblemindedness. Whether these trends will continue is an open question which Sir Alexander Carr-Saunders discussed in his opening remarks. He did not think that the trends could be safely ignored. He had no doubt that there are these differences in intelligence and fertility between different social groups, and innate intellectual efficiency is often associated with qualities of particular value to the community. How this national intellectual endowment can be conserved is a problem requiring unbiased unemotional scientific appraisal by sociologists, psychologists, and statisticians. This sentiment was echoed by Sir Cyril Burt, who pointed out that although there is general agreement about the methods and interpretation of the results so far achieved, there is no good direct evidence of a decline in the average intelligence quotient from one generation to the next. Such studies as have been done have been obscured by sociological difficulties such as migration, and fresh efforts are needed.

[1] [illegible] 1946, ii, 52, 204; Jan. 4, p. 36.

Prof. L. S. Penrose raised the possibility of restitution ctors which must have been at work to counterbalance e influence of differential fertility-rates over the past undred years. Recessive genes may be important in e genetic background of geniuses, whose deviation om the norm may also be evident in a diminished rtility. There is, too, an analogy between intelligence nd stature, in that a negative correlation between height nd size of family has been shown to exist in Toronto hildren of twenty years ago; yet a height survey ecently undertaken has shown a rise, not a fall, in the verage height of the Toronto children of today. The indings in intelligence-test results may be partly explained by a negative association between test score and order of birth, since the achievement scores in a family tend to decrease from oldest to youngest. Later speakers stressed the importance of nutritional factors in the explanation of the Toronto results. Prof. Godfrey Thomson agreed that much could be done by cultural and educational improvements. On the other hand, the matter could be put to the test by direct comparisons between generations. Some studies, he said, are already under way, and preliminary results are not reassuring. The full analysis of the results of the large-scale studies will be awaited with much interest and perhaps a little trepidation.

MEDICAL SUPPLIES

EVEN nowadays, when much of the cost falls on the individual pocket, the national bill for drugs and other medical supplies is large. From April, 1948, when everyone will pay an all-in weekly contribution, it is likely to be at least as heavy. Indeed, experience in other countries where national medical services are already in action suggests that one of the problems we shall have to face, if possible before the appointed day, will be a heavy increase in the demand for medical supplies. On the second reading of the National Health Service Bill Mr. R. Sargood suggested that the annual cost of hospital supplies alone would be about £20–£25 million, and he was anxious that there should be bulk purchasing. For each region to have its own organisation would, he held, lead to overlapping and variation in the standard of equipment.

On Dec. 2 Mr. A. M. Skeffington tried to induce Parliament to discuss the subject in more detail, but was baulked for want of a quorum. Speaking from his wartime experience as assistant director of medical supplies at the Ministry of Supply, he affirmed that if the needs of the new National Health Service were to be satisfied promptly there must be a superdirectorate with authority to coördinate the efforts of the "small, highly competitive and even antagonistic firms" of which the industry is largely composed.

Weight is added to Mr. Skeffington's argument by the situation mentioned in the House of Commons by Mr. de la Bere, member for Evesham, in whose constituency there lies a dump of ex-American medical equipment. This, *he said*, is worth about £1 million; and there is every reason to suppose that its value is really much more. Hospitals have known of it and been trying to get at it for some time now, and both the Ministry of Health and the Ministry of Supply (who are the temporary owners) are anxious that they should make use of it. They are held up, however, by the fact that the Ministry of Health, never having had to deal with stores on such a scale, has in fact no adequate machinery for doing so. The equipment is stored in 100 large hangars, jammed to the roof with crates full of equipment and drugs; and these crates are in no order, with few labels and no inventory —just as they were left by the departing Americans, whose natural instinct was to get rid of the stuff quickly and get home. To the civilian mind the problem is somewhat daunting; but, after all, during the war far bigger ones were dealt with by the R.A.O.C. almost as a matter of routine. Since it seems that the Ministry will eventually have to handle stores on a very large scale, this might be a good moment to establish an organisation. It would first have to take over and cope with the stores in Worcestershire and elsewhere, and would then carry on in more normal manner with the medical supplies which will be needed by the National Health Service. At the moment there must be a large number of ex-officers who are experienced in attending to vast quantities of stores, and it should be comparatively easy to find the right people for doing the work.

Mr. Skeffington also wanted to see the standardisation of equipment, which had proved so successful in war, developed to meet the needs of peace. This proposal is being tackled by the British Standards Institution, who at the suggestion of the British Hospitals Association have set up a committee to go into the problem (*Lancet*, Jan. 25, p. 164). A start has already been made with the institution's published specifications for gas-cylinders and anæsthetic apparatus, hypodermic syringes, stretchers, and stretcher-carriers, and at the suggestion of Sir Alfred Webb-Johnson, P.R.C.S., a standard for apparatus for fluids for intravenous administration is now being prepared. In other countries the national standards organisations are undertaking similar work. At a conference held by the institute on Jan. 14 the chairman, Sir Clifford Parsons, F.R.S., said that most of the difficulties of bulk buying, which had not always proved as advantageous as was expected, could be overcome by the use of British Standards.

> "It is not necessary," he explained, "that standards should require a precise representation of articles but the essentials with which the articles have to conform may be made standard. Standardisation does not necessarily lead to regimentation, nor to exact similarity if it is carried out intelligently and confines itself to such requirements as are essential. It is probable that there are quite a number of items of equipment in hospitals which do not lend themselves to standardisation, or for which standardisation is undesirable. On the other hand, there does appear to be a very large field from which advantages should be obtained."

The new committee has an urgent and important task in hand, and its recommendations will be awaited with interest both by the executants and the administrators of the National Health Service.

TOXICITY OF THIAMINE

SOME unpleasant reactions and two deaths have now been reported after the administration of thiamine hydrochloride intravenously and by mouth. The various manifestations have been classified as toxic and anaphylactic.[1] Nausea, sneezing, dyspnœa, urticaria, and asthmatic attacks have been seen, and Mills,[2] Leitner,[3] and others have noted a thyrotoxic syndrome with nervousness, tremor, tachycardia, and sweating. Steinberg [4] reports three cases of herpes zoster following thiamine administration; one of these patients was receiving the vitamin by mouth, and another developed the condition a second time after a second course of thiamine.

The thyrotoxic reaction, Leitner suggests, is due to overdosage. Mills [5] saw many examples of this reaction in Panama in patients who had previously been severely deficient in thiamine; in one woman the symptoms developed after a $2^1/_2$ weeks' course of 10 mg. daily. The normal daily requirement of thiamine varies, but it is less than 5 mg.; overdosage in therapy is so common that it must be supposed that supersaturation, with or without faulty excretion, causes the thyrotoxic symptoms and not simply an overdose. When the vitamin is withdrawn the nervousness and other symptoms disappear. The anaphylactic phenomena seen in patients receiving the vitamin by *injection* are of all grades of severity, from sneezing to anaphylactic shock and death within

THE STORY OF THE KING'S FUND

1897–1947

FIFTY years ago the prognosis for many of the volun-ry hospitals was poor. Demand for their services had l to rapid expansion in the nineties. Their future was enaced by financial instability as it has never been enaced by plans for nationalisation. Appeals for help ere sporadic, uncoördinated, and aimed at meeting nmediate crises rather than at establishing a sounder ate of financial health. Wards were opened on the roceeds of a special drive for funds, and closed again lmost before they were fully in use.

For the sick who needed hospital treatment the only lternative was admission to the institutions maintained y the guardians under the poor-law and by the Metro-olitan Asylums Board in London—a prospect from hich all but the most necessitous shrank. While ousing and domestic conditions were then more favour-ble for the care of the sick in their homes, district urses and trained private nurses were few, and the need or maintaining the bed-complement of the voluntary hospitals was perhaps as urgent as it is today. If the demand was less insistent that was due to remnants of the old prejudice against hospitals—a legacy from the days of sepsis and of surgery without anæsthesia.

BEGINNINGS

Meanwhile, the preparations for the Queen's Diamond Jubilee were in hand and the Prince of Wales was considering what cause was most worthy to be adopted in commemoration of it. One suggestion came from Sir Henry Burdett. He had made the great hospitals of London his special concern, but his four-volume work on *Hospitals and Asylums of the World* shows how wide were his studies. He insisted on the need for sound administration and control of expenditure, and prepared a scheme for a central hospital fund for the metropolis. The need, the hour, the advocate, and the patron thus came together, and the body which was later to be known as King Edward's Hospital Fund for London came into existence.

The first appeal for funds, a letter from the founder dated Feb. 3, 1897, which was published in all the London newspapers, met with a good response, and at a meeting in May the Prince was able to report that over £130,000 had already been received. "Naturally, everybody will ask when we have got a sufficient sum, 'What are you going to do with it? How are you going to spend it?'" said the Prince. "That is a very grave question . . . it will never do for us to give money right and left to hospitals which are in need. It will be necessary for us to investigate the state in which these hospitals are, to find out those which are in most pressing need of assistance, and also to form some opinion as to the state of efficiency in which they at present exist and how the management is carried on. The subject is one that will require the most mature consideration."

The early meetings were held at Marlborough House, the council being limited by the number of chairs which could be set around the dining-room table. Lord Lister presided over the distribution committee which was responsible for making grants—always on a constructive basis, and not as a means of making up leakages. For instance, the London Hospital was encouraged by a promise of an annual grant of £5000 to spend £100,000 of its own invested funds in bringing its equipment up to date.

One of the failings of the time was the isolation of the hospitals. They were applying the method of trial and error to many variations of the same problems, and were failing to learn from the successes and failures of their neighbours. The King's Fund broke in on this isolation not only by building up a central reserve of capital from which regular grants could be made, but also by requiring efficiency in organisation and adequacy in accommodation and equipment of hospitals receiving its grants. Its reports, based on Sir Henry Burdett's statistics, have for fifty years given hospital administrators a means of comparing their own institution with others of a similar nature.

WAYS AND MEANS

By 1946 the generosity of donors and subscribers, together with munificent legacies, had brought the capital fund up to £5 million, while no less than £12 million had been distributed to the hospitals of London. How was this achieved?

By December, 1897, the total receipts had risen to over £227,000. This sum included nearly £35,000 raised from hospital stamps[1] issued in commemoration of the Diamond Jubilee. A Coronation gift brought in about £124,000. From donors in Canada came £400,000, and from India £15,000. A bequest for £250,000 followed. By 1905 the Fund had an assured permanent income of £50,000 a year, and the founder lived long enough to see an annual distribution of £150,000. During the next decade many large donations and legacies were made, including one of £324,000 from Sir Julius Wernher and one of £150,000 from Isabella, Dowager Countess of Wilton. The stress of the 1914–18 war bore heavily on the hospitals and increased their claims. In 1918 the joint committee of the Order of St. John of Jerusalem and the British Red Cross placed £250,000 at the disposal of the Fund, and in 1920 alone over £700,000 was distributed.

The Fund's system of annual visits to hospitals and of special visits before a grant is made towards a particular project has possibly achieved sounder and more lasting results than any attempts to impose a rigid code on the hospitals could have done. The practice of appointing one medical and one lay visitor for each visit matches the system of honorary medical staff in partnership with a lay committee which has achieved so much of value in the voluntary hospitals. The visitors are not primarily technical experts and do not act as inspectors. They are chosen as being people who are likely to bring to hospital problems a considered judgment enriched by experience in other fields of public life, though some are closely associated with the management of individual hospitals. In visiting a hospital they ask questions prompted by the conditions they meet on their visit, and on subjects chosen for special inquiry. Their impressions are reported in confidence to the Fund, and their reports, collected and summarised year by year, have offered a pointer to the directions in which help is most needed in the interest of efficiency, and have led to the publication of recommendations on such subjects as the supervision of nurses' health, hospital diet, standards of staffing, and the employment of domestic staff.

The Fund also finances special services such as the Emergency Bed Service[2]; the Nursing Recruitment Service, which has guided over 10,000 prospective student nurses into the hospital training-schools; the Radium Pool; and the new system of bursaries in hospital administration.

THE NEXT FIFTY YEARS

The fiftieth anniversary of the Fund coincides with the end of an era and with acceptance of a new conception of hospital provision. If the National Health Service can conserve the best of the voluntary and municipal systems, and can obtain the staff needed to give it life, the hospitals of this country might become, as Burdett said of the voluntary hospitals in an earlier epoch, "the wonder of foreigners and the just glory and pride of the British nation." From this point of view it is important that the Act, while providing for maintenance from public moneys, leaves the way open for supplementation from voluntary sources. The "over and above," the humanising touches which can come only from voluntary gifts, will be needed more than ever. There is always apprehension that a State service, and particularly one which is partly on an insurance basis, will by force of circumstances become a minimal service. In no other field, whether that of transport and communications, the provision of fuel, or even of education, could reduction to a minimum be more directly disastrous to the men, women, and children of this country than it would be in the field of medicine and public health.

---

[1] Some of these stamps are being used to decorate the booklet *Today and Tomorrow* on the work and aims of the King's Fund, which has been issued this week.

[2] See *Lancet*, Jan. 18, p. 109.

The King's Fund will have in hand some £300,000 a year, the greater part of which has been spent in annual maintenance grants to hospitals, to supplement and humanise the national hospital service in the London regions. Its Act of Incorporation empowers it to apply its funds "in or towards the support, benefit or extension of the hospitals of London . . . (whether for the general or any special purposes of such hospitals) and to do all such things as may be incidental or conducive to the attainment of the foregoing objects."

Details of the Fund's programme for the future must, to some extent, await the pattern of things to come. But already it has shown its trend in encouraging the new methods of hospital treatment which medical science has opened up, and in providing better facilities for training all grades of staff. Nothing which would help to relieve the present pressure on hospital beds, the shortage of nursing and other staff, the plight of the chronic sick and advanced cases could be alien to it. The rehabilitation and development of convalescent homes and the provision of special equipment and amenities where they are most needed are already occupying its attention.

On its fiftieth birthday we wish the King's Fund godspeed in the belief that its influence on the quality of the hospital services in the London regions will be as important during the next half-century as it has been in the last.

SPECIAL DIETS FOR INVALIDS

THE PROCEDURE EXPLAINED

THE following correspondence has passed between Sir Edward Mellanby and Mr. Strachey.

Dear MINISTER,—I am writing to you in my capacity as chairman of the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council. As you know, this committee was formed seven years ago at the request of the Minister of Health, the Secretary for Scotland, and the then Minister of Food, Mr. W. S. Morrison. Since then this same committee has functioned continuously under successive Ministers—Lord Woolton, Lord Llewellin, Sir Ben Smith, and yourself—and until the last few weeks there have been few complaints directed against this branch of your Ministry's work. I think you will agree that this is a noteworthy achievement considering the onerous, and often invidious, duties of the committee and is in marked contrast to experience in the first European war when invalid and other claims were a major difficulty in working food-rationing plans, and even at one stage threatened to wreck the scheme. When I have reviewed the hard, disinterested, and very competent service given by its members, and in an outstanding degree by its secretary, Professor Himsworth, and also by Professor Davidson in Scotland, I could not help feeling surprised at how little their work was known or understood. There can be few instances in which the work of a whole department of a ministry, apart from routine administrative duties, has been planned and carried on for so long by an honorary committee entirely outside the ministerial organisation itself.

The committee has not only advised your Ministry on thousands of individual appeals against the rationing regulations for invalids, on appeals from commercial food interests against restrictions on their supplies, given authoritative opinions on requests from industrial bodies and trade unions for special consideration, and undertaken negotiations with professional bodies on behalf of the Ministry, but it has also entirely devised the present system of invalid rationing down even to its administrative details.

I am sure you will appreciate that the members of the committee, being busy and distinguished men, are beginning to wonder how long their services will be required. They appreciate, of course, that no such medical man could undertake the functions which they now discharge as a body; and I, as their chairman, may perhaps be permitted to add that I know of no other group of men in this country who have either the status or the knowledge to take their place. Realising these points, and knowing that their duties will not continue indefinitely, the committee would no doubt be prepared to continue, but they do feel in need of reassurance on two points.

First, the committee would like to know if you still desire their services. If so, they would appreciate a public statement that the Government has confidence in them. Perhaps you might consider it appropriate to make such a statement in the House when you deal with the matter of invalid rationing. It would certainly be appropriate, although I realise it might be impracticable, if past Ministers of Food were to associate themselves with such an expression of appreciation.

Secondly, the committee would like to know whether the situation regarding food-supplies is still such that you would wish them to continue on the same strict principles which were necessary under the exigencies of war. Hitherto, such has been the food situation that the committee has had to formulate its advice in accordance with the following general principles:

(*a*) that extra rations should only be granted to invalids on the grounds of proven therapeutic necessity;

(*b*) that extra rations could not be spared for comforts;

(*c*) that, in deciding between competing claims for the limited supplies of food, preference should be given to those categories of invalids who are capable of being restored to health, or preserved, by means of diet, as active workers;

(*d*) that extra rations should not be granted on vague general grounds, such as debility or general ill health, but only when there were precise indications that certain foods were specifically necessary for the patient's treatment.

(*e*) that only in exceptional cases could the committee advise you to exercise your prerogative of granting compassionate rations.

These are hard principles; and the members of my committee, while appreciating their necessity, have disliked applying them. As physicians they know that, although the extra rations desired by the patient may be of little or no material benefit to him, the refusal of such rations may cause very real psychological distress. But because of the food-supply situation they have had no option in such cases but to advise refusal. Are they to understand that, if you still desire their services, the food situation is still such that, it is necessary for them to continue to be guided by the same strict principles?

London, S.W.1, Jan. 9, 1947. E. MELLANBY.

Dear Sir EDWARD MELLANBY,—Thank you for your letter of Jan. 9, to which I hasten to reply.

Let me say at once that I value intensely the work of yourself and your colleagues of the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council. I do not see how any Minister of Food could carry on the medical side of food-rationing without the help of such a body. As you say, it is a unique but exceedingly valuable feature of the present arrangement that an independent honorary committee entirely outside the ministerial organisation itself is responsible for this side of our work.

I also agree with you that the present membership of the committee is authoritative and eminently fitted to perform its duties. I welcome the opportunity to make these views public, which will be given me by a question put down by Sir Ernest Graham-Little which I shall be swering in the House of Commons next Wednesday, n. 22.

I need hardly tell you that I do desire the continued operation and assistance of the committee. I realise arduous and self-sacrificing work which it has per-med, but I must appeal to the committee to continue perform its functions while our food difficulties ntinue.

Finally, I come to the points raised by you as to whether me relaxation of the very stringent principles under ich the committee works might not now be permitted. nfortunately, the food situation, especially in regard to e particular foodstuffs which I take it are most often commended, such as butter, eggs, and meat, has not t improved. In all the circumstances, I am inclined to ink that we cannot yet make any marked changes in e terms of reference of your committee. On the other and, I do think that when your committee sits in what I ight term its function as a Court of Appeal against its vn regulations as applied by my divisional food officers, might now begin to take a more lenient view of indi-dual applications: and I would trust that such a relaxa-on would help your committee in its arduous and often npleasant work.

It is, of course, still vitally important to prevent a eneral relaxation in the granting of extra foodstuffs to atients, such as did tend to occur this autumn in the ase of milk. It would undermine our entire rationing ystem if it became possible to obtain, say, double the ormal milk ration by means of a complaint to a general ractitioner about feeling overtired or other undefined ymptoms.

Ministry of Food, Jan. 14, 1947. JOHN STRACHEY.

In reply to a request by the British Medical Association, he Ministry of Food has described in detail the procedure or dealing with applications for extra rationed foods on nedical grounds. The following are extracts.

Routine Cases

The procedure in routine cases is for the form R.G.50 or medical certificate to be scrutinised on presentation at the food office for obvious clerical errors, illegible signatures, and anomalies such as the classification of a patient for extra milk under class 1(c) without any classification for extra eggs. Queries of this nature are, as far as possible, dealt with immediately and the wishes of the doctor ascertained. Applications on which no questions arise are granted immediately, and the necessity for speed in arranging for patients to be able to get their extra supplies has been stressed. Cases which must be referred to higher authority are forwarded immediately, and, when applicable, extra supplies are granted at once, either in accordance with the instructions that have been issued or under the food executive officer's powers of discretion.

Special Cases

Applications for extra foods, or for extra quantities of foods, that are not covered by the advisers' standing recommendations and Ministry instructions, are all treated as special cases. Food executive officers have no powers of decision and the applications must be forwarded without delay to divisional food officers. Divisional food officers are not empowered finally to reject any application that is supported by a medical certificate, but they are informed, both by their experience and by information passed to them by headquarters, of the requirements and views of the advisers and, therefore, they ensure as far as possible, by reference back to food executive officers or doctors, that applications include all the required information. This procedure does, of course, in practice dispose of a number of applications.

In general all non-routine cases are received at the headquarters of the Ministry, where the department concerned is in continuous and close touch with the Ministry's advisers through the Ministry's Scientific Adviser's Department.

Since the appointment of the Advisory Committee in January, 1940, a number of precedents have been established. Applications which are clearly covered by precedent are promptly granted or rejected, or, if necessary, further information is requested. Any case, however, in which there is the slightest doubt whether an exact precedent has been established, cases in which the applicant is dissatisfied with a previous ruling, and all cases specifically made under paragraph 19 of MED2 are referred to the Scientific Adviser's Department for special consideration by the Advisory Committee.

The Advisory Committee advises the Minister on the best disposal of the limited amount of foods available for invalids. In respect of the special applications referred to them by the Ministry they advise on the priority to be accorded to each on the basis of the statement of the particular case set out in the medical certificate and of the foods available. Applications from England, Wales, and Northern Ireland are sent in the first instance to Prof. H. P. Himsworth in London; applications from Scotland to Prof. L. S. P. Davidson in Edinburgh. If the application concerns a matter on which the committee has already given general guidance a written statement of the reasons for or against granting the particular application is prepared and, if agreed to by another member of the committee, forwarded to the Ministry of Food. If the application raises a new point it is referred to the whole committee, advice on the general principle being, if necessary, obtained from professional bodies, or, in the case of unusual illness, from other persons with expert knowledge.

General

In practice the Department always accepts the advice which is given and no officer of the Ministry is permitted to adjudicate on the medical evidence given in any case. This does not prevent them, however, putting into effect the known views of the Advisory Committee, but the principle which has been followed is that all lay officers who handle applications for extra foods on medical grounds do so essentially in the capacity of a secretariat for the Ministry's medical advisers.

Reconstruction

TRAINING SCHOOLS FOR NURSES

NEED FOR NEW METHOD OF FINANCE

FROM A CORRESPONDENT

THE inauguration of the National Health Service offers a chance of separating the finance of the nurses' training schools from the finance of the hospitals. This would go a long way to give nursing a new start and lay aside a whole group of handicaps under which it labours today. If nursing is indeed a profession, does it not stand to reason that the nurses' training school should, like the medical school, draw its money, in part at least, from educational funds rather than from moneys voted for the relief of the sick?

PRESENT STATE OF AFFAIRS

The "apprenticeship system" which is so strongly established in this country—as contrasted with American practice—has great advantages and has contributed to the high standard of actual bedside manners, particularly in the larger training schools. But it is apt to subordinate the interests of the student to the interests of the hospital as such. Moreover, it has opened the way for hospitals to become training schools on inadequate grounds: sometimes they have been too small to give comprehensive experience; sometimes the ratio of trained staff to student nurses, or of nurses to patients, has been too low; and the quality of training is apt to suffer accordingly. It is by no means uncommon to hear of cases where the training of the individual nurse has been sacrificed to the needs of the hospital. Thus a girl who is already a qualified children's nurse and is seeking to complete her training at a general hospital too often finds herself called on to help out with the children's ward—this being the one type of hospital work of which she has already had ample experience. Help in an occasional crisis is one thing, but the frequency with which such things now happen is not really defensible. It is common to find that the needs of the training school for proper accommodation and necessary facilities play second fiddle to other requirements of the hospital.

Now all this is very largely a matter of finance. So long as the finance of the training school is inextricably bound up with the general finance of the hospital, the nation." From this point of view it is important that the Act, while providing for maintenance from public moneys, leaves the way open for supplementation from voluntary sources. The "over and above," the humanising touches which can come only from voluntary gifts, will be needed more than ever. There is always apprehension that a State service, and particularly one which is partly on an insurance basis, will by force of circumstances become a minimal service. In no other field, whether that of transport and communications, the provision of fuel, or even of education, could reduction to a minimum be more directly disastrous to the men, women, and children of this country than it would be in the field of medicine and public health.

The King's Fund will have in hand some £300,000 a year, the greater part of which has been spent in annual maintenance grants to hospitals, to supplement and humanise the national hospital service in the London regions. Its Act of Incorporation empowers it to apply its funds "in or towards the support, benefit or extension of the hospitals of London . . . (whether for the general or any special purposes of such hospitals) and to do all such things as may be incidental or conducive to the attainment of the foregoing objects."

Details of the Fund's programme for the future must, to some extent, await the pattern of things to come. But already it has shown its trend in encouraging the new methods of hospital treatment which medical science has opened up, and in providing better facilities for training all grades of staff. Nothing which would help to relieve the present pressure on hospital beds, the shortage of nursing and other staff, the plight of the chronic sick and advanced cases could be alien to it. The rehabilitation and development of convalescent homes and the provision of special equipment and amenities where they are most needed are already occupying its attention.

On its fiftieth birthday we wish the King's Fund godspeed in the belief that its influence on the quality of the hospital services in the London regions will be as important during the next half-century as it has been in the last.

SPECIAL DIETS FOR INVALIDS

THE PROCEDURE EXPLAINED

THE following correspondence has passed between Sir Edward Mellanby and Mr. Strachey.

Dear MINISTER,—I am writing to you in my capacity as chairman of the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council. As you know, this committee was formed seven years ago at the request of the Minister of Health, the Secretary for Scotland, and the then Minister of Food, Mr. W. S. Morrison. Since then this same committee has functioned continuously under successive Ministers—Lord Woolton, Lord Llewellin, Sir Ben Smith, and yourself—and until the last few weeks there have been few complaints directed against this branch of your Ministry's work. I think you will agree that this is a noteworthy achievement considering the onerous, and often invidious, duties of the committee and is in marked contrast to experience in the first European war when invalid and other claims were a major difficulty in working food-rationing plans, and even at one stage threatened to wreck the scheme. When I have reviewed the hard, disinterested, and very competent service given by its members, and in an outstanding degree by its secretary, Professor Himsworth, and also by Professor Davidson in Scotland, I could not help feeling surprised at how little their work was known or understood. There can be few instances in which the work of a whole department of a ministry, apart from routine administrative duties, has been planned and carried on for so long by an honorary committee entirely outside the ministerial organisation itself.

The committee has not only advised your Ministry on thousands of individual appeals against the rationing regulations for invalids, on appeals from commercial food interests against restrictions on their supplies, given authoritative opinions on requests from industrial bodies and trade unions for special consideration, and [illegible] taken negotiations with professional bodies on behalf of the Ministry, but it has also entirely devised the present system of invalid rationing down even to its administrative details.

I am sure you will appreciate that the members of the committee, being busy and distinguished men, are beginning to wonder how long their services will be required. They appreciate, of course, that no single medical man could undertake the functions which they now discharge as a body; and I, as their chairman, may perhaps be permitted to add that I know of no other group of men in this country who have either the status or the knowledge to take their place. Realising these points, and knowing that their duties will not continue indefinitely, the committee would no doubt be prepared to continue, but they do feel in need of reassurance on two points.

First, the committee would like to know if you still desire their services. If so, they would appreciate a public statement that the Government has confidence in them. Perhaps you might consider it appropriate to make such a statement in the House when you deal with the matter of invalid rationing. It would certainly be appropriate, although I realise it might be impracticable, if past Ministers of Food were to associate themselves with such an expression of appreciation.

Secondly, the committee would like to know whether the situation regarding food-supplies is still such that you would wish them to continue on the same strict principles which were necessary under the exigencies of war. Hitherto, such has been the food situation that the committee has had to formulate its advice in accordance with the following general principles:

(*a*) that extra rations should only be granted to invalids on the grounds of proven therapeutic necessity;

(*b*) that extra rations could not be spared for comforts;

(*c*) that, in deciding between competing claims for the limited supplies of food, preference should be given to those categories of invalids who are capable of being restored to health, or preserved, by means of diet, as active workers;

(*d*) that extra rations should not be granted on vague general grounds, such as debility or general ill health, but only when there were precise indications that certain foods were specifically necessary for the patient's treatment,

(*e*) that only in exceptional cases could the committee advise you to exercise your prerogative of granting compassionate rations.

These are hard principles; and the members of my committee, while appreciating their necessity, have disliked applying them. As physicians they know that although the extra rations desired by the patient may be of little or no material benefit to him, the refusal of such rations may cause very real psychological distress. But because of the food-supply situation they have had no option in such cases but to advise refusal. Are they to understand that, if you still desire their services, the food situation is still such that it is necessary for them to continue to be guided by the same strict principles?

London, S.W.1, Jan. 9, 1947. E. MELLANBY.

Dear Sir EDWARD MELLANBY,—Thank you for your letter of Jan. 9, to which I hasten to reply.

Let me say at once that I value intensely the work of yourself and your colleagues of the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council. I do not see how any Minister of Food could carry on the medical side of food-rationing without the help of such a body. As you say, it is a unique but exceedingly valuable feature of the present arrangement that an independent honorary committee entirely outside the ministerial organisation itself is responsible for this side of our work.

I also agree with you that the present membership of the committee is authoritative and eminently fitted to perform its duties. I welcome the opportunity to make these views public, which will be given me by a question put down by Sir Ernest Graham-Little which I shall be

HEALTH CENTRES ATTACHED TO TEACHING SCHOOLS

But the utilitarian outlook, though proper to these ard times, is not enough. Besides discovering how to upply medical care economically we have to find out how o improve its quality; and from the first there must e some centres which are in no sense makeshift but are eliberately designed as the best we can devise. These hould serve the purpose both of experiment and teaching, nd should therefore be attached to the undergraduate eaching schools.

In the neighbourhood of each teaching school there night be a district where the students could see general practice at its best and in process of development. Such a district, with a population of perhaps 100,000 and containing half a dozen health centres, could be the field of study for the professor of social medicine and his staff, who would work in conjunction with the health-centre practitioners in teaching, in research, and in improvement of the service.

It may be many years before the ordinary health centres elsewhere can do more than concentrate on the work in hand; but in the health centres of a designated teaching area the staff could be supplemented from university and trust funds, and many valuable experiments could be made without throwing an undue strain on the participating practitioners. For example, within the designated area periodic examination of all the people could be undertaken, accurate morbidity statistics could be collected, the technique and results of health education could be explored, and medical liaisons with local industry could be formed. At the same time the field of general practice could be demonstrated to the student in a way that has hitherto been impossible, and his outlook could thereby be given a new and preferable orientation.

In a word, the health centres attached to a teaching school could from the beginning be given a special opportunity to live up to their name—to promote the positive health of the people under their care. In so doing they would enable us to form opinions as to what should or should not be undertaken later elsewhere.

This would, of course, carry the corollary that, as soon as circumstances allow, centres embodying all that has been found best in these prototypes must be planned and provided as widely as possible. Otherwise we should only be preparing for the next generation of general practitioners further frustrations. If we are to show the medical student how efficient and attractive general practice can be made, we must not deny him the use of the same methods in his own practice.

PRIORITIES

Naturally, for many a long day, priorities will still have to be observed. The case for the establishment of centres is, and will continue to be, stronger in some areas than others. It would be idle to attempt now any detailed assessment of future needs; but we may hope that well-designed and well-equipped centres will prove a potent means of attracting the best of the new doctors (and perhaps some of the older ones, too) to areas where they are most required. Therefore consideration should be given to the early establishment of centres in unattractive and under-doctored areas.

Another pre-eminently suitable field for experiment will be the new satellite towns. Here there should be a good opportunity for testing new methods of approach to health problems, both preventive and curative, and for finding ways whereby the health services may best be integrated into the life of a newly developing community.

PERSONAL HEALTH AND PUBLIC HEALTH

The health-centre project again exposes the impermanence of the old boundaries between the provinces assigned to the medical officer of health and the practitioner. The M.O.H. was supposed to concern himself with preventive medicine, and the practitioner with curative medicine. But the real boundary, in so far as there must be one, lies between personal health and public health. The M.O.H. is primarily interested in the *community*, and therefore in epidemiology, in environmental standards, and in general health education. The practitioner's particular duty, on the other hand, is to do all he can for his *individual patient*, and he will fail therein unless, besides curative medicine, he practises preventive medicine and what we have termed functional medicine—the promotion of the highest level of function possible for the individual.

The health centre, as we have been describing it, is essentially a place where personal health is to be sought —through curative, preventive, and functional medicine. It is dedicated to the individual patient or person, not to the community, and only by a series of historical accidents does it come at all within the realm of the doctor who specialises in public health.

It is natural that the keen M.O.H., now accustomed to administering hospitals and remedial clinics, should tend to see it as an extension of his own department, affording him a welcome opportunity of closer study of the environmental and social aspects of public health. Indeed, by taking away from the local health authority its function of providing a hospital service, and placing on it the new task of establishing, maintaining, and largely staffing the centres, the National Health Service Act lends colour to this idea that these centres are part of the local public-health service; and the M.O.H. may be forgiven for thinking of the practitioner's quarters as a mere annexe to the local-authority clinic. Nevertheless the personal-health service is *not* a part of the public-health service, however closely the two should be connected. To regard it as such is to invite difficulties, and we feel sure that the best work for health centres will be done by the M.O.H. who, in the temple of Personal Health, is content to serve as provider and arranger, taking care to reserve his vestments of a chief priest for the temple of Public Health where his supremacy is unquestionable.

GROUP PRACTICE

Another fundamental question that arises is the relation of the patient to the doctors working in a group. The traditional foundation of the personal-health service is a contract between the patient and a single doctor. Is this basis to be changed when the service is embodied in a health centre? Will the patient cease to be the patient of a particular doctor and become the patient of the group?

We should be sorry to see so great a departure from former custom. Hitherto the patient has had the benefit of two kinds of care. From his family doctor he has had the care of an adviser who accepts responsibility as an individual, and often as a personal friend. When this adviser has felt that his help was insufficient, he has handed over the patient to a second kind of care—that of a group of people forming the staff of a hospital. Here, though admitted in charge of a particular member of the staff, the patient is really under the care of the group as a whole, many of whose members share the responsibility for him.

Those who think that a patient attending a health centre should be the patient of the whole group are bringing the hospital conception into general practice, to which it is foreign; and they may be depriving the patient of the comfort of committing himself and his fortunes to a single person whom he knows and trusts. Might it not be better if, on the contrary, we increased rather than diffused the responsibility of the individual practitioner for his patient? Ideally, should we not arrange that even when he transfers his patient to the matron and others responsible for the standard of training have their hands tied, and must continually give way to what are represented as more urgent demands.

It is significant that the one training school where this separation has been to some extent attempted is the Nightingale School at St. Thomas's, where the school has its own endowment and a separate set of accounts. "The distinctive advance made by the Nightingale School"—to quote Worcester's book on *Nurses and Training*—"was due to its independence. From the first its liberal endowment has allowed it to hold fast to its educational ideals. And there it has been proved that the best nursing service in a hospital can be given by pupil nurses of a school that has for its main purpose their education, and not the pecuniary advantage of the hospital."

A DIFFERENT METHOD

The case for drawing on educational funds for a proportion of the assessed cost—not only of the teaching staff but also of the maintenance and remuneration of the pupil nurses—is therefore strong. It would perhaps be unreasonable to urge that the entire cost should be so met, since it is appropriate that the hospital should recognise by a financial contribution the benefit it gets from the presence of the training school within its walls.

The appropriate source of the educational moneys seems to be either the University Grants Committee or the Ministry of Education—supplemented, perhaps, as such funds might well be, by grants for special purposes and by grants from the great hospital trusts—King Edward's Hospital Fund for London and the Nuffield Provincial Hospitals Trust. A stimulus would thereby be given to those responsible for organising the training schools: but more than this, they would be given, in respect of the educational responsibility, a status which they at present lack. It would not then be necessary for the training school in need of a better supply of textbooks, or whatnot, to argue the claim in competition with the urgent need for repairs to the domestics' furniture, or for the matron to be told that the reprinting of the prospectus of the training school to bring it up to date was something of a luxury and must wait.

These instances of petty but serious handicaps under which the nurses' training school labours under the present régime are not far-fetched: they are everyday occurrences in many hospitals. Nor will they disappear with the mere assumption by the Ministry of Health of financial responsibility; for the hospital management committee is to have a free hand to manage its own affairs within its budget, and there is never likely to be money enough to meet all demands. The fact is that the object of the training school and the object of the hospital are not identical, though of course they overlap. It is too much to expect the hospital, which has to find money for all sorts of worthy objects of its own, always to be fair to the training school whose aims may often seem by comparison to be of less immediate consequence. We shall not be likely to get things in their proper proportion so long as the present financial tangle is preserved.

WHAT SHOULD BE DONE

The right solution appears clear enough. The training school should make up its own accounts, and it should carry the whole cost of teaching staff and also of the maintenance and remuneration of the student nurses. In return it should secure on the one hand a grant from the Exchequer, via the Ministry of Education or the University Grants Committee, and on the other an agreed amount from the hospital in recognition of services rendered. It does not very much matter how the amounts are calculated, or in what proportion, so long as the object is kept in sight—namely, that the requirements of the training school are not subordinate to those of the hospital.

The need for some such change was recognised by th Athlone Committee in its report of 1939, though th merely suggested that payment should be from th Exchequer. It was not then foreseen that the Exchequ would become responsible for hospital finance, and if i the new circumstances a distinction is to be maintain we must go a little further than the Athlone Committe and stipulate that the payment ought to come from th Exchequer by another route than through the Ministr of Health.

The introduction of the National Health Servi should enable us to bring about easily and smoothl a change which might well do more than any oth single step to secure the student status of the nurse i training.

Health Centres of Tomorrow

VI—CONCLUDING REFLECTIONS

AN American visitor the other day thought it odd us to be giving health centres so large a place in o plans for the National Health Service. "As far a I can see," he said, "you haven't got any yet. In t States we should handle this differently: we shou want to see some centres in operation before decidin to have a whole lot more."

As things stand, however, neither he nor anyo else need fear that health-centre practice will be general adopted before there has been time to test its value. the irony of fate, the era of planning which has n dawned in this country coincides with an era of mater scarcity; and the plans for creating a really good medi service depend, like most other plans, on whether, despi wars and rumours of war, the new techniques of producti can create the world of abundance that science h promised. Till that happens it will be impossible to bui large numbers of health centres all over the count and even our experiments may often have to be ma with makeshift apparatus.

Nevertheless there is a strong case for taking th experiments very seriously, and for making them extensive and convincing as we can. On the long vie the really well-equipped health centre may prove to the ideal base for the general practitioner of the futu and we need pilot models now. On the short and ut tarian view, a less ambitious type of centre might b valuable means of economising medical resources w these remain straitened. Even a makeshift centre, hous in old buildings or military hutments, and using surp war equipment now in store, might enable practition to do more and better work in less time and with effort; and without some such saving in medical m power there will certainly not be enough doctors provide a genuinely comprehensive medical service.

Since the State is offering medical care to everybo it must spend enough to make that care efficient; an health centres fulfil their promise the money devo to them will be very well spent.

Concentration of the work of six doctors at a ce should mean overhead costs lower than those of separate practices. With nurses, secretaries, and t phonists at hand, and the social services on tap, practitioner should be relieved of much non-med labour. The burden of clerical work and record-keep can be largely shifted to clerks. Ready access to techn aids and the help of colleagues should save time trouble. Much duplication of equipment and inst ments can be avoided, while standardisation and b buying will reduce expense. As in large partnersh arrangements for free afternoons, nights off duty, sufficient holidays can obviate the chronic fatigue wh prevents so many practitioners from making the best of their skill.

In England Now

A Running Commentary by Peripatetic Correspondents

IT requires some time in general practice before one compiles a working terminology. With growing relief one abandons the academic approach for expressions which doctor and patient can understand.

Suppose, for example, that you are faced with a child with a high temperature. To announce hesitantly that it is rather difficult to say at the moment but that pneumonia may well develop serves truth but is not helpful. The confident statement, however, that this is a severe chill is immediately acceptable, and allows for a really remarkable recovery by the next day, or alternatively a definite localisation of the trouble. Thus a chill may settle on the chest, even to the extent of the lungs becoming congested. Other possibilities include a "chill on the kidneys," or, more simply, a "chill round the water-works."

It is important to avoid such terms as "neurosis" or "anxiety state." These not only annoy the patient but often lead to vague circuitous conversations which completely alienate him. Neurasthenia, on the other hand, or its little brother, nervous debility, are solid and understandable. From these it is fortunately possible to make a passable recovery in a short time.

The word "injury" carries profound significance in legal circles, so it is best to adhere to such a classification as "bruised foot," "sprained foot," "fractured foot," or "septic foot." Incidentally, for goodness' sake get an X-ray film taken of any injury round the ankle which may conceivably lead to litigation. It may not do the patient any good, but it will save you from looking a fool some day in the witness-box.

Skin conditions are rather well known to the public and not interchangeable. Hence one must consider carefully scabies, ringworm, impetigo, eczema, and even psoriasis. Dermatitis, another implement for litigation, is to be avoided. When in doubt, eczema will do as well as anything until you know what the diagnosis really is —if you ever do.

* * *

I confessed to a literary friend that there were times when the urge to write was so insistent that I did not feel happy until my thoughts were on paper. Did he have similar literary crises? "Yes," he replied, "I do get that very feeling and invariably in an acute form on the day before I start a cold. I fancy it must be the manifestation of an outpouring of adrenaline."

That set me thinking. I could not agree with the idea of the crisis depending on adrenaline, for no palpitation, sweating, or other physical discomfort accompanies the urge. Those indications impress themselves on me just before I get up to make a speech but not when I feel I must put pen to paper. No; it must be something which overcomes inhibitions and enables the brain to pour out the product of its workings. We are all aware of men of genius who were the victims of drug-addiction, under the influence of which they often wrote masterpieces, but that is the exception, and in fact we do not know what physical conditions lead to moments of inspiration. We do know something of the psychical motives of literary power but it is rather degrading to analyse them too much.

During the few hours preceding the onset of a severe cold in the head I have often had the feeling that I was much better than usual, that I was "on top of the world." That must surely be due to the absorption of small quantities of the poison generated by the microbe or virus which is responsible for the cold. It is as it were a homœopathic dose of a living vaccine. Surely it should be possible to extract the substance which causes this euphoria and to use it medicinally? Everyone is aware also that in phthisis the patient may feel that he or she is improving although the physical signs indicate the reverse. Here again there must surely be some protein derivative either in the microbe itself or manufactured in the tissues by that microbe which affects the cerebrum benevolently. If one could only isolate that substance it might prove to be the finest pick-me-up or tonic ever. You will ask your patient: "How do you feel today?" and get the answer: "Jolly rotten—very depressed." "Well," you will reply, "just take a small dose of this tuberculin-extracted tonic and you will feel splendid." Only I feel sure that in the initial language of today we should refer to it as T.E.T.

* * *

Family life seen through the eyes of the Ministry of Health and the Central Council for Health Education appears to consist in one catastrophe after another. Their film, *Your Children and You*, leaves one with the impression of crashing crockery, harassed parents, screaming children being sent to their rooms, favourite toys being removed, and battles over food. Even the domestic dog turns and bites the baby. It is true there are admirable sequences showing real insight into children's feelings. These include shots of the baby's view from the pram, small boys helping their fathers dig, small girls washing their dolls' clothing, and some excellent advice on how to handle the older child when a new baby is on its way. These are happy and helpful scenes. But the fact that I can recall only one smiling mother and countless harassed ones indicates the film's overall mood.

We start with the landlady and the parents being woken in the night by a screaming baby, and we are at once warned that having a baby means work, work, work: warned too that if we don't master him, he'll master us—no mention of fun and pride, or the fascination of seeing an infant grow and become an individual, or the subtle changes of feeling which parents undergo when their children are growing up. The relationship depicted between parents and children is often disciplinarian, rarely that of mutual enjoyment. There is no understanding that with parenthood, as with all professions, unless we get satisfaction and pleasure from it we are unlikely to be successful. On the contrary this presentation is so largely in terms of blood, sweat, and tears as to be most discouraging to the beginner. Perhaps the Royal Commission on Population will ban it on these grounds.

When the film concentrates on how to keep children happily occupied it is good: when it tells us how to deal with difficulties it is frankly deplorable. When the three-year-old is found playing with the carving knife, instead of his being offered some alternative plaything and his interest diverted, the knife is wrenched from him with the expected screams. Granny, who takes his side, is held up as a monster from whose spoiling ways the child must at all costs be preserved. The child who prefers pudding to veg. is given the option of veg. or nothing. No give or take, no finding out what suits, above all no humour. When the child of five years wets herself mother is reprimanded for inadequate training. Naughty children, naughty mothers, naughty grannies!

To many whose work lies with parents and children, especially those who have got into difficulties, this film will seem a calamity. The very fact that about half of it is very good makes the resulting mixture even more unfortunate, since the bad parts will appear more plausible. No doubt its sponsors on reading these criticisms will remark that it is hopeless to attempt anything in this field because all the experts disagree. But the B.B.C. has shown us how a nationalised or governmental body can deal with controversial topics—by giving exponents of different points of view an opportunity of expressing them and by avoiding any suggestion of authoritative statement. So far from discouraging the Ministry from making films on child upbringing, therefore, I hope that others will be made, presenting so far as possible the divergent points of view now current. And I am willing to bet that the one which is psychologically most accurate, and therefore most helpful, will be the most popular.

* * *

Teaching physiology to second-year medical students has its lighter side in our college. Recently I was asked, "Sir, what is pH—is it a substance like an enzyme?" I clutched the lab bench for support, and trotted out what every medical student should know about H-ion concentration. The oaf apparently digested this information in toto, and I felt justly proud of having got something home into his hemispheres. Two or three days later we were discussing blood-groups. I gave a snappy survey of the Rh factor and its importance. I chanced to encounter the oaf afterwards and brightly asked him if he grasped the idea of the Rh factor. "Oh, yes, sir, it's got some connexion with pH, hasn't it?" Well, he may be right, but should a Qh (or qH) be discovered, God help us!

hospital he should continue to watch over that patient's interests, just as the captain of a ship remains on the bridge when a pilot is taking his vessel through difficult waters ?

All the same, if half a dozen practitioners are to work together in the partnership of a health centre they will fail in their duty towards one another if they do not develop a certain responsibility for each other's patients ; and in a good health centre the patient, though he gains all possible advantage from having his *own* doctor, will also enjoy the protection of the group as a whole and of any member whom he encounters.

The development of a group spirit among the doctors in a health centre is indeed a necessity ; for the biggest advantages to be expected from inviting several practitioners to work under one roof are the intangible advantages of professional and personal association. Here it may be relevant to recall Bion and Rickman's requirements for a good group spirit,[1] which included—

(*a*) a common purpose ; (*b*) common recognition of the "boundaries" of the group and their position and function in relation to that of larger units or groups ; (*c*) the capacity to absorb new members and to lose members without fear of losing group individuality ; (*d*) freedom from internal groups having rigid boundaries ; (*e*) each individual member of the group is valued for his contribution to the group and has free movement within it, limited only by the generally accepted conditions devised and imposed on the group ; (*f*) the group must have the capacity to face internal discontent and must have means to cope with it.

GENERAL PRACTICE

Those who see the patient as belonging to the group rather than to his "own" doctor usually have in mind a partnership in which the partners develop specialised functions and the patient (as in a hospital) goes to the ones most skilled in managing his ailment. In our third article we contested this view that the health centre should become a group of specialists forming a minor Mayo Clinic, and argued that each member of the staff, though he might develop special aptitudes, must continue to be a truly general practitioner.

Those who favour a high degree of specialism among practitioners often claim that this is the only way to keep them interested in what is otherwise apt to be a dull occupation. We believe that general practice need not be dull, but can and should, under proper conditions, be capable of giving a full and satisfying life. Specialisation should only be necessary to the extent that it enables the individual to enhance his contribution to the group and so more effectively allows him to fulfil criterion (*e*) above. It is possible that, in the course of cultivating such a special interest, the practitioner may find that he has an aptitude for his chosen specialty which justifies his eventual translation to the purely specialist field, but he should be encouraged to take this step rather because it offers better chances of his using his particular talents than because it promises much better financial reward. There is much to support the argument of those who say that general practice is itself a specialty, demanding a great deal of knowledge, skill, and judgment from those who take it up. The renaissance of general practice, they feel, will be achieved not by making each practitioner a graded specialist in something else but by asking a high standard in his own specialty.

Whether it is or is not desirable for him to make a hobby of some particular kind of work, the G.P. still has wide scope for the exercise of his talents. He will always have great responsibilities.

To him comes the patient with his earliest presenting symptoms. Many of these will only be manifestations of minor illness or injury. Yet the proper and skilful handling of these ailments—learnt best, and perhaps only, in general practice—may often prevent their developing into more serious troubles. Especially this true in the case of minor psychological disorders And always among these seemingly unimportant symptoms there will be the first warning signals of the commencement of more serious illness, the early detection of which must essentially remain the task of the general practitioner. He must as well continue to shoulder the responsibility for the early diagnosis and prompt handling of surgical and medical emergencies, and should be able to call on the nursing and laboratory facilities that would enable him to deal efficiently himself with the pneumonias, with cardiac failure, and with diabetic coma, without necessarily losing touch with his patients in a specialist hospital.

The general practitioner will remain the close confidant of his patient. He it will be who will decide when hospital investigation is needed or consultation should be sought. He should be given every opportunity of easy personal access to the consultant services. His position of trust, the "family-doctor relationship" he has with his patients, makes him the most suitable person to advise on matters of health as well as illness. Ideally he should be the doctor giving continuou advice through all ages on the problems on which hi patients so often need help—problems which may rang from those of diet and clothing to those of genetics an family relationships. Apart from the judicious educatio of his patient in healthy living, the practitioner has th duty to see that he has the full benefit of preventi methods such as immunisation. Much of the antenatal pædiatric, school, and industrial work now done by full time medical officers should and can be restored to th general practitioner, and obstetrics will still be practise by those interested in it.

The fact that so much more can nowadays be done fo people means that the general practitioner has a mor important rôle in seeing that it is really done. Th health centre of tomorrow must give him all he needs t realise the great potentialities of what is still to man the most fascinating and useful branch of medicin It remains for the profession to convince itself and t persuade others that the vigour of a country's medic service is measured by its strength in general practic from which all other branches spring.

The new National Health Service must not becon just a new method of paying for the general practitioner services : it must give him new advantages, enlar his capabilities, and restore some of the opportuniti which general practice has—with the advance of medici —been lately in danger of losing. To do this it will necessary to explore and utilise to the full the conceptic of group practice in health centres.

But the B.B.C. has shown us how a nationalised or governmental body can deal with controversial topics—by giving exponents of different points of view an opportunity of expressing them and by avoiding any suggestion of authoritative statement. So far from discouraging the Ministry from making films on child upbringing, therefore, I hope that others will be made, presenting so far as possible the divergent points of view now current. And I am willing to bet that the one which is psychologically most accurate, and therefore most helpful, will be the most popular.

* * *

Teaching physiology to second-year medical students has its lighter side in our college. Recently I was asked, "Sir, what is pH—is it a substance like an enzyme?" I clutched the lab bench for support, and trotted out what every medical student should know about H-ion concentration. The oaf apparently digested this information in toto, and I felt justly proud of having got something home into his hemispheres. Two or three days later we were discussing blood-groups. I gave a snappy survey of the Rh factor and its importance. I chanced to encounter the oaf afterwards and brightly asked him if he grasped the idea of the Rh factor. "Oh, yes, sir, it's got some connexion with pH, hasn't it?" Well, he may be right, but should a Qh (or qH) be discovered, God help us!

Letters to the Editor

HISTOLOGY OF THE COMMON COLD: AN APPEAL

SIR,—Apart from the work of Hilding[1] we have found no references to careful studies of the histological changes produced in man by the common-cold virus. Further information about such changes would be of great value in the studies of this disease now being conducted here.

Many people are killed in accidents or die suddenly from other causes; many people have common colds, especially at this time of year: there must therefore be many who die suddenly in the early stages of a cold. We should be very grateful to any pathologist who could let us have small pieces of nasal mucous membrane from cases of accidental or other sudden death where it was known that the subject was in the first week of a cold. Material should be placed in saturated corrosive sublimate solution containing 10% of formalin (10% formaldehyde) and sent to this address. One of us would also be glad to attend personally any autopsy on such a subject taking place in the London area.

National Institute for Medical Research, Hampstead, London, N.W.3.

TREATMENT OF TUBERCULOSIS

SIR,—One thing that appears to be quite clear from this correspondence is that the authorities entirely disagree. While Dr. Houghton and Dr. Corrigan (Dec. 14) find it necessary and advisable to use the "harmless" amphetamine for blotting out the deleterious and often disastrous apprehension of active interference, which is generally felt by patients in modern sanatoria, Dr. Simmonds (Jan. 11) finds that "the majority of patients here accept the need for active interference without emotional upset." Dr. Howard (Jan. 4) is of the opinion that amphetamine is not harmless, and that some patients have an individual idiosyncrasy to it which is far greater than with other drugs; the makers of amphetamine question this view (Jan. 18).

The surgically minded tell us of the benefits to be derived from immobilising the lung by artificial pneumothorax, inflating the peritoneal cavity, paralysing the diaphragm, and cutting out portions of the bony thorax; yet perhaps the least mobile part of the lung, the posterior aspect of the apices, is most often attacked by the disease, while during and following such procedures the *other* lung is given double the work to do. Is it that, ignoring the diseased lung, they have adopted for the lesser affected lung Mr. MacMahon's advice (Jan. 25): "Physicians and nurses who are to have charge of tuberculosis cases should, by breathing and physical exercises, fully develop their chests and lung capacity, for it seems to me that lungs which are thoroughly aerated must have a better chance of resisting the disease."

We are indebted to Dr. Temple Clive (Jan. 25) who very ably sums up the difference between treatments in the various institutions: "Let us not forget that the quiet and peaceful surroundings of the true sanatorium have as prominent a place in the treatment of the tuberculous as the noisy and restless environment of the surgical wards of the chest hospital."

Though opinions conflict on these matters it is generally agreed that resistance to the disease is lowered by poverty and overwork in cold, damp, ill-ventilated, or overcrowded dwellings; yet we still see millions expended on sanatoria and mass radiography which could more profitably be used in building up resistance by improving *the food and homes of the people.*

We also know that by far the greater majority of the people who contract tuberculosis recover from it without the disease being specifically treated or even recognised except by chance or mass radiography, and that the disease has progressively diminished with improvement in the social welfare of the people. Would it not therefore be cheaper and more reasonable to expend our efforts in this direction rather than waste them in expensive, ineffective, inefficient fractional measures?

Birmingham.
JAMES F. BRAILSFORD.

SIR,—Dr. Clive's axe, though possibly somewhat blunted, can still be wielded to good advantage; he does well to draw attention (Jan. 25) to the increasing of surgical interference in pulmonary tuberculosis, the "noisy and restless environment of the wards."

The true value of collapse therapy has yet to assessed; as far as I am aware there is still no statistical proof on an actuarial basis that cases need this therapy have end-results even as good as th not needing it. I would be the last to deny th collapse measures have often been brilliantly successf but with the present demand, both inside and outsi the profession, for more and more collapse therap there is need for a firm restatement of the fundament importance of rest and fresh air. Rest must be not o physical but mental. The quietude of mind induced b old-fashioned sanatoria was the basis of many success cures; and there was little need in those days to f back on amphetamine or other cerebral stimulants allay the feeling of "apprehension and alarm" wh has been mentioned in this correspondence.

Lip-service is always paid to the value of long-co tinued rest; but very few institutions have really carri out this treatment, although it is the bedrock of tuberculosis therapy and the only measure which h stood the test of time. Since Lillingston and Rivi raised their voices in its favour few in this country ha emphasised the value of a long period of rest; and these days of restless unceasing search for new metho of collapsing the lung, or draining cavities, or raising t diaphragm, or removing ribs, I feel that collapse measur already at hand should be appraised anew.

J. H. CRAWFORD
Douglas House, Bournemouth.
Medical superintendent.

GENTIAN VIOLET IN GASTRO-ENTERITIS

SIR,—I have had considerable success in the treatment of gastro-enteritis, where no specific organism is involved, with gentian violet in keratin-coated capsules. Th should be combined with a bland bismuth mixture as sedative for the gastric mucosa. The dose for an adult is *1 grain twice daily given as four gr.* 1/4 capsules. For a child half this dose and for an infant a quarter. Youn children with teeth are apt to bite the capsules, an unless this is prevented by administering the capsules i jam and tickling the child the treatment may fail.

The treatment is of almost immediate benefit to mo *cases and a* few hours suffices to produce well-mark improvement. It should however be continued for day or two to avoid relapse.

I have found it of great use in the present widespre gastro-enteritis at all ages, though I have not had t opportunity of trying it in a bad epidemic of neonat diarrhœa. In the few cases of the latter that I have tri it on it has been successful, and in my opinion it deserv further trial. I consider it far superior to the sulpho amides as a bacteriostatic in the gut.

Lytham.
ROBERT F. E. HARRINGTON.

DOCUMENTATION

SIR,—In the third of your series of articles on *Heal Centres of Tomorrow* (Jan. 18) you imply that R.A. records during the war were written by hand. Aft four years of Army psychiatry during which I saw ma R.A.F. cases I whole-heartedly agree that Air For medical records are good. The reason however is th they are *typewritten.* All special investigations a reports are also typed on the same record, and it is th possible to read a R.A.F. case-paper in a fraction the time which it takes to peruse other forms of recor which often consist of a multitude of odd-sized pieces paper with every variety of scribble. As to the accura of the typewritten records, which you mistrust, I fou very few errors; and the simple check of initialli after perusal should be sufficient to guard against maj mistakes.

My experience of *handwritten case-records* of chro patients in mental institutions leads me to the sa conclusions. The value of these records is severe limited by the difficulty which one experiences in readi them, written as they are by many hands.

In my opinion the typewritten flimsy is the ide solution. The importance of uniform paper size cannot over-emphasised, and all additional reports and inform n should be copied on to the same record. In addition special summary form at the front showing special atures, such as operations, X-ray of chest. or vaccina- on, is essential. It is high time that ordinary doctors well as consultants demanded the use of efficient ethods commonly required by business concerns of uch less national importance. The setting up of the ew health centres should give the patient the benefit f a modern record system without saddling the doctor ith the burden of additional clerical work.

GERMANY

SIR,—We want to plead for the better provision of good therapeutic material for the Germans of the British zone. While we cannot claim to have made a detailed study of what drugs are available, we have been in Germany for a considerable time, and our dismay at their inadequacy has grown steadily. Having but just returned from leave in England, we are frankly ashamed to think that, whereas in Britain life-saving and limb-saving drugs such as penicillin may be prescribed for simple sore throats and other trivial ailments, they are denied to all Germans save those with acute gonorrhœa. Presumably nobody denies our responsibilities towards the population of the zone, and we wonder if there can be more than a handful of your readers who would not share our sentiments in this matter had they been timidly approached by eminent German doctors with a request for some penicillin to save a life or a limb which would otherwise perish. We make the plea that British medicine should restrict or ration its use of this and comparable drugs in order to help our fellows.

We are aware that the press generally makes life in Great Britain appear intolerably hard just now, and occasionally features life in Germany as just a little more intolerable. As two medical men who know both worlds and have seen the slow hunger and helplessness that have so embittered our ex-enemy protectorate we venture to cast a little shame on us all and beg that we be allowed to relapse into Christianity, which we have fought for, and so long-denied in our dealings with these people.

N. SAUNDERS
Lübeck. L. F. LEVY.

_ In our issue of Jan. 25 (p. 158) an appeal for money to buy penicillin for Germany was made by the Ecumenical Refugee Commission, 21, Bloomsbury Street, London, W.C.1.—ED. L.

CHILBLAINS

SIR,—I have been using calciferol in the treatment of chilblains for several years, and agree with Dr. Phelan (Jan. 25) that it is a most potent curative agent; but it seems to be less valuable in prophylaxis.

I have always administered calciferol in the form of high potency 'Ostelin' tablets (50,000 I.U. per tablet): 1 tablet daily is given, irrespective of age, until cure or marked improvement is apparent—which is often in less than a week. After that 1 tablet is given three times a week for several weeks, to prevent relapse. In severe cases in adults I sometimes start by giving 1 tablet twice daily. Most cases are quickly cured by this treatment, and no ill effects have been noticed.

Troon. JAMES ROSS.

PAYING THE ANÆSTHETIST

SIR,—Anæsthetists will, I am sure, appreciate the emphasis in your leading article of Jan. 4 on their responsibilities at a surgical operation.

The wide range of the anæsthetist's duties, which is still not recognised, will not, I fear, of itself attract enough suitable recruits to the specialty. To ensure that they are forthcoming the remuneration will have to be considerably improved.

Outside the teaching centres it is exceptional for an anæsthetist, however competent, to be able to earn a living solely by the practice of his specialty, and nowhere does he enjoy a reward comparable to that of his colleagues otherwise engaged. The tradition of high surgical fees and low anæsthetic fees will not be ended until the advantages of having skilled anæsthetists are appreciated. And who will champion the anæsthetist's interests?

The addition of higher anæsthetic fees to the already high cost of surgery would, I believe, be unfair on most patients, to whom the cost of surgery must already be well-nigh insupportable. How then is the anæsthetist to receive a proper reward for his services?

An operation requires a team consisting of surgeon, anæsthetist, and assistant, upon whom responsibility devolves in that order, with, as you have emphasised, a close bracketing of the first two. It would seem reasonable to charge the average patient an inclusive fee for the team's services and to remunerate its individual members out of that sum by a division which fairly reflects the responsibility of each. Opinions will differ as to the division, but long experience and much thought lead me to suggest that a fair division would be: surgeon 60%, anæsthetist 30%, and assistant 10%.

The institution of a scheme such as this would, I believe, be gratefully welcomed by the public; while adequately remunerating the surgeon it would establish the practice of anæsthesia on a financial basis satisfactory enough to attract sufficient able recruits.

Bournemouth. S. F. DURRANS.

CHEST DISEASE IN RAND MINERS

SIR,—An error has crept into your annotation of Dec. 28 (p. 952). You say, "The miners are examined every three years after an initial examination . . ." As a matter of fact all miners were examined every six months during the period covered by the Miners' Phthisis Medical Bureau Report—the three years ended July, 1944. Since then the Act of 1946 has modified this proviso, and miners with less than six years' continuous or cumulative service need only be examined once every twelve months. However, miners with continuous or cumulative service of more than six years must still be examined every six months, as has been the law for many years past.

This matter is of great interest to those concerned with the control of silicosis. In the opinion of all of us who have had lengthy experience with this disease, the initial examination, by eliminating persons who are likely to be more than ordinarily susceptible to dust inhalation, plays a not inconsiderable rôle in reducing the incidence of silicosis; and the periodical examination, by influencing the retirement from the industry of a certain number of early cases of silicosis, is often an important factor in preventing the progress of the disease or at least greatly slowing it down.

A. J. ORENSTEIN
Rand Mines Ltd., Johannesburg. Chief medical officer.

SIR,—It might be instructive to compare the conclusions drawn in your annotation of Dec. 28 with those we carried away from visits to various hospitals and mines in Johannesburg and district in October, 1944.

In the first place, the statement "no form of mass radiography has yet been introduced" seems peculiar, as we saw the miniature radiography equipment installed at the Witwatersrand Native Labour Association Ltd. Hospital. With this equipment the officer in charge of the X-ray department, K. G. F. Collander, told us that he could examine the chests of about 500 natives in a forenoon. We were also led to believe that native workers were examined by X rays at intervals of approximately 6 months, especially those in whom some abnormality had been found. Here we were shown some miniatures of a very high standard, as well as the large plates from the same case.

With regard to the factors concerned in the spread of chest disease, we were told, in the mine we visited, that the air was dried, in an endeavour to prevent the incidence of silicosis and tuberculosis; yet, in almost his next breath, our guide drew our attention to the large water tanks throughout the mine, all open to the air. On the actual drilling face we found a thick moist warm fog through which it was impossible to see for more than a yard or two; to us this appeared to be the perfect place for the production of silicosis, yet there was no evidence of any prophylactic face-masks being worn.

We note with interest your statement that any miner found to have phthisis is forced to stop underground work. We were informed (though our information may have been false) that native workers suffering from phthisis were given a choice similar to that allowed to cases of silicosis. As the pension awarded was stated to be equivalent to a year's pay, the natives almost invariably chose to continue work in the mines, a choice tantamount to signing their own death warrant, since tuberculosis is known to have a high mortality among natives.

In conclusion, a word about the treatment of native workers suffering from chest diseases. During a brief visit to the W.N.L.A. Hospital, no case of chest disease was seen, but at the Infectious Diseases Hospital at Rietfontein we found that the admission of more than minimal numbers was impossible owing to shortage of staff. In a further hospital near the centre of the city this shortage of staff was responsible for several new wards for the treatment of tuberculous cases remaining unopened.

London, S.W.10.

J. F. D. FRAZER
J. I. WALKER.

MEDICAL ASPECTS OF MARRIAGE GUIDANCE

SIR,—Dr. Griffith's comprehensive survey last week raises a question which is discussed in the medical press less often than I would wish.

There is general agreement that ignorance of erotic technique among married people is a bad and deplorable thing. The intelligent and sane study of erotics as an art and a source of pleasure and satisfaction seems to me to be the mark of a civilised community, just as is skill in the preparation of food. Yet anyone who attempts to publish an explicit account of the variations and methods of this study is likely to find himself the butt of a silly and humiliating prosecution, in which, as in a recent case where a medical man was prosecuted and resoundingly acquitted, he is liable to find himself in company with the writers of erethistic books on torture and of other paper-backed works which are simply printed symptoms of abnormal behaviour-patterns. Even a work directed wholly to medical readers may not escape criticism.

The real offence lies in directing instruction to the general public at a reasonable price. The idea of illustrating such a work to make it intelligible would raise any publisher's hair. Our own society takes a view which is probably unique.

This is one of the forms of stupidity for which we, or rather our patients, pay in loss of normal enjoyment, and in the guilt and malaise which accompany sexual distortion. The range of normal variation in sexual practice is wide enough to satisfy all but the grossly deranged; but unless they can read French or Latin they have no means of informing themselves.

I wonder how our health would fare if the entity which is optimistically described as "public morality" took the same view of cookery as it does of sexual technique. The anomaly is one which medical opinion cannot itself remove; but medical protest might in time persuade the public at large to remove it.

PHYSIOLOGIST.

THE NURSING CRISIS

SIR,—Your leading article last week cannot claim to be comprehensive in its dealing with this problem of nursing shortage.

You lay emphasis on the disadvantages of the standard Rushcliffe range of salary, pointing out that the policy of uniformity has made it impossible for some hospitals to offer any compensatory advantage. This is not true. The Rushcliffe scale has only established a national *minimum* range of salary. There is nothing to prevent a hospital paying more, except that this extra would not qualify for the 50% grant which the Ministry of Health is prepared to give to cover the increased costs to them by adopting the scale. Less attractive hospitals can, therefore, increase this minimum in order to secure nurses.

Cardiff.

DAVID G. MORGAN.

*** We are obliged to Dr. Morgan for drawing attention to a gap in our article: we should have explained how the minimum scale has come to be regarded as a maximum. He is no doubt technically correct, but the Rushcliffe policy of uniformity is none the less a reality. Though the committee was appointed to draw up "agreed" scales of remuneration, it has used its influence to ensure that its "recommended salaries and emoluments" shall be generally adopted without additions by individual hospitals or authorities. Its attitude was made clear in its first report (1943), which spoke of "undesirable competition for staff between different hospital authorities" and said that "the national *adoption of the scales we have drawn up* will bring such competition to an end."—ED. L.

LEPTOSPIROSIS CANICOLA

SIR,—Dr. Klein (Jan. 4), commenting on the paper by Dr. Baber and myself,[1] states that Professor Lukes was the first to identify *Leptospira canicola*. I should like to point out that I have acknowledged Lukes's pioneer work on Stuttgart disease in a recent paper,[2] but I cannot admit his identification of this organism. The spirochæte found by Lukes and Debrek[3] in th kidneys of affected dogs was called by them *Spirochæt melanogenes canis* and was said to be highly virulen for guineapigs. Later, in 1926, Lukes admitted certai technical errors in his earlier work and implied that th virulence had not been established. I quote from Wirth[4] "Lukes später (1926) selbst wörtlich: 'Wir müssen abe zugeben dass uns die Arbeiten von . . . auf Irrweg geführt haben . . . *so dass wir die Mehrzahl* unsere Versuche weglassen müssen und nur seltene als positi bezeichnen.'"

Although its feeble virulence for the guineapig is on of the major features distinguishing *L. canicola* from *L. icterohæmorrhagiæ*, this somewhat equivocal information does not prove that Lukes was working solely wit the first organism. Again the transmission of Stuttgar disease to animals does not identify the organism in th inoculated material as *L. canicola*. Wirth[5] showe experimentally that rat leptospiræ (which are neve *canicola* strains) could occasionally produce typica Stuttgart symptoms in dogs, and suggested[6] that th symptomatology depended as much on the age an resistance of the infected animal as on the infectin strain. It is of course now well established that Stuttgar symptoms in dogs are usually caused by *L. canicol* but the fact that they can on occasion be produced b *L. icterohæmorrhagiæ* invalidates any claim to identi fication on this ground. Accordingly, I consider tha Klarenbeek and Schüffner[7] who first isolated and sero logically differentiated *L. canicola* must be accorded th credit for its first identification.

The earlier work of Lukes and his colleagues is o sufficient intrinsic merit to obviate any necessity fo a claim which cannot be substantiated; I freel acknowledge that some of the spirochætes seen by Luk as early as 1910[8] *may* have been *L. canicola*.

Central Public Health Laboratory,
Glasgow.

FATAL USE OF A DANGEROUS UNIVERSAL DONOR

SIR,—It is to be hoped that all clinicians who ord or give a blood-transfusion will appreciate the importan of Dr. Tovey's letter (Feb. 1), in which he abho the use of the term "universal donor." It is certainl one which should have been discarded by now, thoug it is still employed quite generally by doctors; an because of unfortunate propaganda it is now well established in the lay mind. Many blood-donors who find th they are not of the "universal group" feel that th are not required, which is particularly unfortunate i the case of group-A donors. As group-A and group people are, roughly speaking, numerically equal, patients were grouped before transfusion the deman for A and O blood could be made nearly equal; peop of groups B and AB can of course be used to provi plasma. *With donor panels decreasing* in most region the urgent need for group-to-group transfusion cann be too strongly emphasised.

It is perhaps unfortunate that the human organis can survive *considerable insults in respect* of incompatible transfusion; I know of a group-O patient wh was recently given in error 2 pints of group-A blood, an who was none the worse for it. The fact that a clinicia

Parliament

THE SCOTTISH BILL IN COMMITTEE

ON Jan. 28 a standing committee of the House of Commons began the consideration of the National Health Service (Scotland) Bill under the chairmanship of Mr. G. MATHERS. The people of Scotland, Lieut.-Colonel WALTER ELLIOT declared, had themselves done a great deal to provide effective health services, and he feared that the Bill's policy of centralisation might slow up this process. Therefore, in their criticisms and amendments of the measure, the Opposition would seek rather to lay emphasis on that danger.

THE HEALTH SERVICES COUNCIL

Mr. J. S. C. REID moved an amendment to clause 2 designed to make the ambit of the Health Services Council as wide as possible so that it could advise upon services not yet in operation as well as existing ones. Mr. J. WESTWOOD accepted the amendment in the spirit in which it was moved, as helpful in providing a more comprehensive service. The amendment was agreed to. He also accepted an amendment, which was agreed to, providing that the council should be allowed to appoint its own members on the standing advisory committees instead of their appointment being made by the Secretary of State after consultation with the council.

Colonel ELLIOT moved an amendment to omit the proviso enabling the Secretary of State to refrain from laying before Parliament the report of the council if he was satisfied that it would be “contrary to the public interest.” The danger of unauthorised disclosure, he held, was completely covered by the Official Secrets Act. But, Mr. WESTWOOD insisted on retaining this safeguard, and the amendment was negatived.

On the question that clause 2 stand as amended part of the Bill, Mr. Westwood, without pledging himself to accept any particular suggestions, promised to consider any proposals to secure as comprehensive and as good a health service as could be provided for Scotland. In setting up the advisory committees he had in mind the appointment of medical, nursing, hospitals, mental health, dental, and pharmaceutical committees; and it might be that the idea of other committees would crop up. Because of the special health problems in those areas a Highlands and Islands committee would also be set up. Each standing advisory committee under clause 2 would be empowered on their own initiative to advise on any matters connected with their special services. Both the Secretary of State and the main council might refer to a standing advisory committee.

TEACHING AND RESEARCH

Mr. REID, in moving the omission of subsection (2) of clause 3 which throws upon the Secretary of State responsibility, in providing hospital and specialist services, to make available facilities for clinical teaching and research, affirmed that if there was to be a flourisl school of medicine there must be close and frie relations between the university and the hospita which the clinical teaching took place. The Secretar State and his permanent officials were not the r people to deal with the four universities in Scotl and dictate to them what clinical teaching they ough have. The Scottish universities would be put int position of inferiority and have to take what was g to them. If the Bill passed in its present form Mr. viewed with apprehension the future of Scotland resort for foreign students of medicine. Sir JOHN GRA KERR, F.R.S., pointed out that a university or med school was not independent of the teaching hospi they were inextricably entangled one with the other constituted a unity which was important to the wel of the whole health service.

Dr. STEPHEN TAYLOR felt that the English Bill a considerable advantage over the Scottish Bill the way it treated its teaching hospitals. There w great deal to be said for a teaching hospital ha a considerable degree of autonomy. The commi should take special thought for the protection of re because it was desirable to give the rebel in medi the maximum opportunity for developing himself from excessive supervision. But Dr. Taylor did not t that the proposal to omit this subsection achieved object. The Secretary of State clearly must have duty of considering the size of the medical labour f which he would require in the future. Therefore, he m make some kind of decision as to how many pe were needed in the medical school, and how m clinical teaching was required. Dr. Taylor had he *it said that owing to the popularity of the Edinbu* school the ratio of students to clinical teaching in Royal Infirmary had become increasingly unsatisfact He thought that the regional board might also not a desirable body to nominate the teaching hospit The Secretary of State could take a nation-wide in deciding how big a medical force would be nee But once the teaching hospitals had been chosen Taylor thought it would be an improvement to them the kind of autonomy they had under the Eng Bill.

Mr. G. BUCHANAN, Joint Under-Secretary of S for Scotland, said that the Bill did not affect teac at all; teaching remained the duty of the univers The Secretary of State provided the facilities for teach but in no sense did he interfere with what had alw been the historic privilege of the universities. Scottish set-up, he thought, was superior to the Eng one. On this issue the local authorities, the Bri Medical Association, and the universities were in princ agreed. The only body against the scheme was British Hospitals Association. In Scotland the teach hospitals played a much larger part in the provisio bed accommodation than in England. If the teach hospitals were set apart from the ordinary regio work a serious disservice would be caused. It proposed to set up for the teaching hospitals a sepa board of management which would not be responsibl the regional board. He hoped to see teaching hospi expanded rather than contracted. It was proposed give the universities representation on every board management, and the only condition imposed was t if there was a substantial amount of teaching the uni sity should have a larger representation. The Gove ment went further still and said that the staff should represented on the board. These were more import and far-reaching proposals than the English ones. amendment was negatived by 34 votes to 18.

QUESTION TIME

Special Diet for Invalids

Colonel M. STODDART-SCOTT asked the Minister of F how many times the Food Rationing (Special Diets) Advis Committee had met during the last six months of 19 and how many medical men were present on each occasio Mr. JOHN STRACHEY replied: Applications for special rat for individual patients are not taken to the committee a whole, but are sent by the secretary to at least two mem of the committee, the two members most qualified to d

camp he came to this country in 1939. Eventually he became assistant medical officer of health to the West Hartlepool corporation, an appointment which he held until his death.

Apart from medicine, Lissauer's interests were centred in his home and in the faith of his forefathers. His mind possessed a sparkling quality which, together with his urbane manner and sensibility, always suggested a Gallic origin, perhaps the result of a French bias in his early education. His death was keenly felt by his colleagues, who salute a life of brave endeavour. He is survived by his wife, Dr. Charlotte Lissauer, of the Middlesbrough school health service, and by one young daughter.

AWARDS

M.B.E.

Major **TURNER MCLARDY**, M.B. Glasg., R.A.M.C.
Major **N. C. WELPLY**, M.R.C.S., R.A.M.C.
Captain **SARDAR AHMED**, I.A.M.C.

MENTIONED IN DESPATCHES

Notes and News

WAR OFFICE DEMAND FOR JUNIOR OPHTHALMOLOGISTS

THE Central Medical War Committee is informed that, because of the shortage of ophthalmologists available for military service, the War Office is prepared to employ, as trainee ophthalmologists with a view to early grading as graded specialists, a number of men who, although not at present of graded specialist status, have held resident appointments for not less than six months in ophthalmic hospitals or ophthalmic departments of general hospitals in the United Kingdom, and are recommended by the ophthalmologists under whom they have worked as being competent to deal with errors of refraction, to perform minor operations of the eye, and to treat the common diseases of the eye.

A large part of the ophthalmic work in the Army falls under these headings, and if men with the limited experience referred to were available to deal with such work, the cases requiring the attention of a fully trained ophthalmic specialist could be concentrated at special centres in the home and overseas commands, and greater economy in the use of the specialist officers would thus be effected.

The Central Medical War Committee is now considering the recruitment of young practitioners whose experience of ophthalmology is such as to satisfy the Army's requirements as stated above. It invites applications from practitioners who will shortly complete junior resident appointments in eye hospitals or eye departments and who would like to undertake their military service at this stage as trainee ophthalmologists. Communications should be addressed to the secretary of the committee at B.M.A. House, Tavistock Square, London, W.C.1.

SCOTTISH NURSING

IN Scotland, as elsewhere, nursing recruitment reflects general labour conditions, being good in times of industrial depression and poor in times of prosperity.

The Scottish Advisory Committee of the Nuffield Provincial Hospitals Trust have lately published a report[1] by their medical committee on hospital staffing which reads like the refrain of an old song. All the usual troubles are there: the proportions of trained staff to total staff, and of nurses to patients, are not high enough; there are too few nurses to relieve during off-duty times and in case of sickness among the staff; the 96-hour fortnight is rarely possible; students suffer strain from combining nursing duties with study, and they do too much domestic work; trained staff who choose to live out do not get adequate allowances; there are few ways of bridging the gap between school-leaving age and admission to training; and the impression that nursing is an overworked and understaffed profession is justifiably widespread.

Cheerfully and calmly the committee set out the known remedies. The 96-hour fortnight should be enforced. The ratio of staffing in the wards of a general hospital or a sanatorium should be 1 nurse to 1·5 patients; in a fever hospital the ratio should be 1 to 2; in a maternity unit or a children's hospital 1 to 1. Much more, and much better, domestic help is needed. They remind hospitals politely of the part parsimonious administration has played in creating the present adverse impression among potential recruits. They suggest that experiments in the three-shift system should be tried. Nurses' homes should be managed with a more liberal outlook, and without irksome regulations. A simple matrix test, employed at Crichton Royal Hospital, has made it possible to recognise early those applicants who will have little difficulty in passing examinations, and it might, they think, be more widely applied. They recommend the block system of training, and advise the employment of orderlies to relieve nurses of unsuitable duties. More use could, they believe, be made of male orderlies, but they do not foresee much scope for the employment of male nurses in acute general hospitals.

It is noteworthy that there is a disinclination among entrants to the profession to become assistant nurses. "Girls who are attracted to nursing as a career want to become State-registered nurses in the full sense of the term, not to become an admittedly inferior type of nurse, expected to spend a considerable part of her time doing domestic work."

---

[1] Nursing Staffing in Hospitals, 1946. Copies may be had from the Secretary to the Scottish Advisory Committee, 10, Duke Street.

The last part of the sentence indicates the light in which the nursing profession at present regards the assistant nurse. The committee suggest that the whole question of the "assistant nurse" should be reviewed—an opinion with which we cordially agree.

A WELL-ESTABLISHED CEREBRAL PALSY UNIT

AT Queen Mary's (London County Council) Hospital for Children, at Carshalton, a cerebral palsy unit, the first to be set up in Great Britain, has been active since 1943.[1] An average of 14 children at a time receive treatment along the lines laid down by Prof. W. M. Phelps, of Baltimore; and many of them improve enough to attend a school for physically defective children, while a few become fit for a normal school life. Most of them are helpless and bedridden on admission, but as they are usually normally intelligent they can learn to manage their disability, in time being able to feed, wash, and dress themselves, and to take part in the communal life of the unit. The unit provides for observation, diagnosis, and intensive treatment in surroundings which maintain the atmosphere of a residential nursery rather than a hospital ward. The numbers under treatment are soon to be increased to 20; and later it is hoped to take 40, and finally 60, when it is estimated that between 120 and 150 could be treated yearly. The head therapist of the unit has had training and experience in the Phelps method of treatment. The education committee of the council have been asked to help in finding suitable schools for children on discharge; and close links are being made with St. Margaret's, the new voluntary school for children with cerebral palsy recently founded at Croydon.[2] Proposals for increasing the staff of the unit are being put before the council.

TEACHING BY FILM

A YEAR ago the Royal Society of Medicine and the Scientific Film Association met to discuss the application of the cinema in medical teaching. A report of the discussion has now been published in a booklet[1] which covers the principles and practice of teaching by film and reveals a strong demand for short silent illustration films in preference to long film lessons. The booklet also includes a list of subjects on which films would be welcomed by teachers of medicine; this will be a useful guide to intending film makers. On Feb. 12 another joint meeting is to be held at the Royal Society of Medicine (5 P.M.), the subject for discussion being the use of filmstrip in medical teaching.

A PATIENT'S VIEW

Mr. Wilson Midgley, editor of *John o'London's Weekly*, has described his experiences in a general hospital ward.[1] With an artist's eye, and a journalist's appreciation of their true interest, he has seen all those daily episodes of the ward that we so easily take for granted, and perhaps even find humdrum. He has translated them into a series of essays, clearly and charmingly written, and though he writes primarily for a public unversed in the ways of hospitals, and perhaps often unduly apprehensive of them, almost every essay contains something, either of praise or well-weighed criticism, which we should heed. Whether he is discussing pain, or the qualities that go to make a good sister, or tepid cabbage, or the folly of nursing old men and boys in the same ward, or whether he is just painting pictures of what he sees about him, he writes with insight.

This is a book from which we may learn what we must alter in the future and what we must resolutely retain. Because of its appreciation of the humanity and humour of the life of a hospital ward it also contains much of interest to the potential patient or the would-be nurse.

Royal College of Surgeons of England

During the next months the dinners held in the college for fellows and members and members of the associations linked to the college will take place on the following Wednesdays at 7 P.M.: Feb. 12, March 12, April 9, May 7, June 11, and July 9.

University of Oxford

On Jan. 23 the following degrees were conferred:

B.M.—Granville Freeman, J. B. Walker, E. J. Madden, John Gask, R. A. L. Leatherdale.

Royal College of Physicians of London

At a meeting of the college held on Jan. 30, with Lord Moran, the president, in the chair, the following were elected representatives of the college: Dr. A. S. Barnes on the court of governors of the University of Birmingham; Sir Reginald Bond on the council of the Professional Classes Aid Council; Dr. W. G. Wyllie on the National Association for Mental Health; and Dr. Janet Vaughan on the advisory board of nursing education of the Royal College of Nursing. Sir Allen Daley was nominated to represent the college at the conference of the Royal Sanitary Institute in June.

The following having satisfied the censors' board were elected to the membership:

D. G. Abrahams, M.B. Camb., W. B. Alexander, M.B. Camb., J. V. Almeyda, L.R.C.P., C. L. Balf, B.M. Oxfd, A. H. Baynes, M.B. Camb., Patricia L. Bidstrup, M.B. Adelaide, J. H. Burkinshaw, M.B. Camb., C. R. Burton, M.D. Toronto, James Carson, M.D. Belf., A. G. C. Cox, M.B. Lond., H. D. Crosswell, M.B. Lond., P. H. Davison, M.B. Birm., John Dean, M.B. Camb., R. B. Franks, M.B. Camb., B. F. Gans, M.D. Lond., R. T. Gaunt, M.B. Sheff., K. B. Gibson, M.B. Lpool, William Goldberg, M.B. Witw'srand, K. J. Grice, M.D. Melb., G. R. Handy, M.B. Lond., Margaret M. Henderson, M.D. Melb., R. A. Henson, M.D. Lond., R. D. Hotston, M.B. Lpool, John Lowe, M.D. Birm., Anne E. McCandless, M.B. Lpool, J. A. Malloch, M.B. Edin., E. P. G. Michell, M.B. Camb., E. P. Morley, M.B. Camb., E. J. Moynahan, L.R.C.P., A. P. Norman, M.B. Camb., Gordon Osborne, M.B. Camb., J. H. S. Pettit, M.B. Lond., W. J. E. Phillips, M.B. Camb., J. R. K. Preedy, M.B. Camb., Frederick Prescott, L.R.C.P., W. A. Pritchard, M.B. Lond., E. G. G. Roberts, M.B. Wales, J. B. Robinson, M.D. Lond., N. A. Rossiter, M.B. Witw'srand, Gregory Shneerson, M.B. Lond., John Simpson, M.D. Durh., Eric Smith, D.M. Oxfd, J. B. Stanton, M.B. Camb., T. H. Steel, M.D. Melb., G. H. Valentine, M.B. Brist., captain R.A.M.C., Albert Venner, M.B. Lond., A. P. B. Waind, D.S.C., M.D. Leeds, C. W. M. Whitty, B.M. Oxfd, M. H. C. Williams, B.M. Oxfd, H. H. O. Wolff, M.B. Camb., Max Zoob, M.B. Lond.

Licences to practise were conferred upon the following 96 candidates (70 men and 26 women) who have passed the final examination of the Conjoint Board and have complied with the by-laws of the college:

D. A. B. Ashcroft, J. H. Atteridge, A. R. Baines, D. C. Barker, Mary E. Benians, N. O. Bennett, P. R. Boyd, G. A. Bracewell, D. C. Bradford, Alison M. Brydone, Joyce M. Buck, Irene M. S. Cade, G. H. Carriett, Kenneth Carter, D. J. E. Cheshire, Jeanne M. Clements, Mary M. H. Cogman, C. I. Cohen, J. J. Content, Edward Coupland, K. S. Daber, Sylvia Danks, Barbara M. Davey, Joan M. Denman, Robert Dryden, K. H. Foord, D. S. Foster, Joan Frankton, Angela D. Fuller, P. R. G. Graham, Gordon Hadfield, M. J. Hargrave, B. M. C. Harris, J. A. B. Harrison, A. J. Harrold, Mary W. Hart, F. C. B. Harvey, Hugh Herbert, G. M. Hopwood, Barbara M. F. Jacobs, K. E. Jolles, R. T. Jones, Basil Karat, R. A. Kershaw, C. S. Kirkham, S. A. Lateef, D. D. La Touche, Norman Lees, Ursula E. K. Leitner, Lillian J. Letty, A. H. Levy, F. M. MacDonagh, Anne J. W. Manley, E. D. Marsh, Stefan Mejzner, Christine L. Miller, L. G. Nicol, Jakob Niwes, C. F. Noon, A. G. Norman, Vivienne Norman, F. G. Orton, Mathoor Panikkar, Enid H. Pettigrew, G. S. Plant, I. R. D. Proctor, D. R. V. Prys-Jones, Harry Rawlings, Michael Redfern, E. N. Rees, D. E. R. Richardson, Kathleen J. Rigg, Diana M. Robinson, Sonia Rollin, G. W. J. Rothwell, C. D. Rushworth, R. A. Ryan, A. I. Sahyoun, Joan Seaman, Henry Shapiro, F. J. Sharrod, J. G. H. Shaw, S. G. A. Shute, N. T. Smith, Joan E. T. Spong, Cynthia F. Stephenson, H. S. Trafford, Maxwell Vites, David Walker, N. H. Warburton, J. C. Ward, P. A. M. Weston, H. D. White, R. M. C. Williams, Elizabeth Williamson, G. M. Woodwark.

Diplomas were conferred jointly with the Royal College of Surgeons on those named in THE LANCET of Dec. 21 (p. 930) and of Jan. 18 (p. 123), and on the following:

D.P.H.—J. B. Bramwell, Alan Butterworth, W. A. Cannell, W. J. Christie, C. W. Coffey, J. S. Coleman, Eveline M. Cumming, O. L. Day, H. McD. Forde, A. H. T. F. Fullerton, Margaret R. Gilmour, D. W. T. Harris, R. A. Hoey, E. I. Holloway, G. J. Laws, C. D. L. Lycett, H. G. Magill, J. E. Masterson, B. U. Meyer, Robert Murray, J. J. O'Dwyer, M. J. Pleydell, Isadore Reubin, Arna E. Rides, R. D. Rutherford, Christina M. Small, T. D. Spencer, M. E. M. Thomas, P. de B. Turtle, G. P. Wallace, W. M. Walsh, E. R. Winton.

D.L.O.—W. F. Dickie Clark.

Pharmaceutical Society of Great Britain

On Thursday, Feb. 13, at 7 P.M., at 17, Bloomsbury Square, London, W.C.1, Mr. H. Davis, PH.D., will speak on Chemical and Pharmaceutical Aspects of Anæsthesia.

Lectures on Child Psychiatry

Dr. Michael Fordham and Dr. R. D. Newton will give a course of lectures on child psychiatry at the West End Hospital for Nervous Diseases, 40, Marylebone Lane, W.1, on Monday and Tuesday afternoons from Feb. 10 to March 4. The course is open only to members of the Fellowship of Postgraduate Medicine, 1, Wimpole Street, London, W.1, where further particulars may be obtained.

Scottish Triple Qualification

The following, having passed the requisite examinations, have been admitted to the licentiateship of the Royal Colleges of Physicians and Surgeons of Edinburgh and of the Royal Faculty of Physicians and Surgeons of Glasgow:

J. D. Bowie, Audry G. Burdett, J. G. W. Cunningham, Matthew Devlin, Pearl I. Evans, William Frame, J. M. Gillies, S. J. Glueck, A. J. Graham, F. H. Hamill, Winifred M. Hiscock, R. J. Kleinglass, George Metz, W. C. Palmer, E. L. Peel, N. W. Preston, I. M. Ratner, J. M. Raynor, Eva Revesz, Stanley Rose, Georgina M. H. Smeaton, Bernard Taylor, W. B. Willder, Richard Wolfson.

Department of Health for Scotland

The Secretary of State for Scotland has appointed Mr. G. H. Kimpton to be an under-secretary in the department in charge of the divisions which deal with health services.

London Hospital Medical College

The Liddle triennial prize for 1946 of £120 has been awarded to Dr. F. O. MacCallum for his essay on epidemic jaundice. Dr. Sheila Sherlock (proxime accessit) has been awarded £50.

Nuffield Fellows from Australia

Winners of 2 of the 12 Nuffield fellowships awarded to ex-Service doctors in Australia last year have left Australia to take up their appointments. Dr. W. J. Simmonds, of Brisbane, holder of a three-year fellowship in physiology, is going to Oxford to work under Dr. F. C. Courtice. Dr. F. L. Ritchie, who holds a one-year fellowship, will take a four-month course at the Brompton Chest Hospital and at Queen Square Hospital for Nervous Diseases in London. He also intends to spend eight months at Sheffield with Prof. C. H. Stuart-Harris.

International Cancer Research Congress

The fourth International Cancer Research Congress will be held in St. Louis, Missouri, from Sept. 2 to 7, under the joint auspices of the Union Internationale contre le Cancer and the American Association for Cancer Research. Dr. E. V. Cowdry, professor of anatomy at the Washington University school of medicine and director of research of the Barnard Free Skin and Cancer Hospital, will preside. Further information may be had from Dr. M. G. Seelig, Barnard Free Skin and Cancer Hospital, St. Louis, 3, Mo., U.S.A.

Blood Shortage in Glasgow

Glasgow is seriously short of blood-donors. War-time reserves of plasma are now exhausted, and not enough donors are coming forward to meet the increasing demand for both whole blood and plasma. Figures given by the Glasgow and West of Scotland Blood Transfusion Service for the week ending Sunday, Jan. 19, show that while the output of blood and plasma, expressed as donors, was 336, the number of donors bled was only 226—a shortage of 110.

Chemists' Federation

At the federation's annual luncheon in London on Jan. 30, Sir Arthur Rucker, deputy secretary, Ministry of Health, expressed his belief that a fine service could be evolved from the National Health Service Act. The patient should, of course, choose his own doctor, "provided that the latest biennial plebiscite of the profession has shown that he is willing to give his advice." Dr. Charles Hill, secretary of the British Medical Association, said that the profession was fighting to prevent its being made into a technical branch of central or local government.

Summer School on Social Biology

The British Social Hygiene Council hopes to hold in Switzerland, during the last fortnight of August, a summer school on Social Biology—its International Aspects. The school *is intended for teachers, social workers, and others* interested in social biology, and it is hoped that there will also be students from other countries. Lectures will be in English. The estimated cost, including travel, board, and tuition, is between £25 and £30.

Early application should be made to the secretary, B.S.H.C., Tavistock House North, Tavistock Square, London, W.C.1.

PENICILLIN FOR INSURED PERSONS.—Penicillin is now sold in two forms—the ordinary yellow form, and "white" penicillin which may be crystalline or amorphous. The Ministry of Health have instructed pharmacists to use yellow penicillin or solution-tablets when dispensing N.H.I. prescriptions for local applications and to reserve white penicillin for eye-drops and preparations intended for injection.

Appointments

EVANS, T. P., M.R.C.S.: M.O.H., Amersham, Chesham, and Beaconsfield.
HAMBRIDGE, RHODES, M.R.C.S.: asst. chest physician, Surrey county council.
LAWRIE, J. H. D., M.D. Edin., D.P.H.: M.O.H., Shoreditch.
MURRAY, CHARLES, F.R.C.S.E.: asst. orthopædic surgeon, Royal Portsmouth Hospital.
STARKIE, COLIN, M.D., B.SC. Manc., D.P.H.: M.O.H., Kidderminster, and asst. M.O., Worcester health department.

Middlesex County Council:

BURNETT, C. W. F., M.D. Lond., M.R.C.O.G.: senior obstetrician, West Middlesex County Hospital.
CALLUM, E. N., F.R.C.S.E., D.T.M.: surgeon, Ashford County Hospital.
CHESTER, A. W., M.D. Durh.: chief asst., obstetric department, Hillingdon County Hospital.
COGHILL, N. F., M.B. Camb., M.R.C.P.: physician, West Middlesex County Hospital.
DAVIES, D. A., M.B. Lond., M.R.C.O.G.: senior obstetrician, West Middlesex County Hospital.
DEANE, M. M., M.B. Melb., A.R.C.P., D.P.M., D.A.: physician, West Middlesex County Hospital.
PEMBERTON, T. M., M.B. N.Z., F.R.C.S.: surgeon, Chase Farm Hospital.
SCHOLEFIELD, JOHN, M.B. Leeds, F.R.C.S.: surgeon, West Middlesex County Hospital.
STEPHENS, T. W., F.R.C.S.E., D.T.M. & H.: chief asst. to thoracic surgeon, Clare Hall Hospital.

Births, Marriages, and Deaths

BIRTHS

BARCLAY.—On Jan. 27, the wife of Dr. G. A. Barclay—a daughter.
GRAHAM.—On Jan. 28, in London, the wife of Dr. Ian Graham—a son.
HARVEY.—On Jan. 27, at York, the wife of Lieut.-Colonel W. G. Harvey, R.A.M.C.—a son.
HILEY.—On Jan. 25, in London, the wife of Surgeon Lieut.-Commander Charles Hiley, R.N.—a daughter.
KENNY.—On Jan. 27, in London, the wife of Mr. W. T. Kenny, F.R.C.S.I.—a son.
KIRSHNER.—On Jan. 29, at Chichester, the wife of Dr. A. Kirshner—a son.
PARTRIDGE.—On Jan. 28, at Worthing, the wife of Dr. A. J. Partridge—a daughter.
PEASE.—On Jan. 29, at Oxford, the wife of Dr. J. C. Pease—a son.
REINOLD.—On Jan. 27, the wife of Dr. D. G. Reinold—a son.
RICHARDSON.—On Jan. 28, at Perth, the wife of Colonel Frank Richardson, D.S.O., O.B.E., R.A.M.C.—a son.
RIGBY.—On Jan. 9, at Lewisham, the wife of Dr. J. P. V. Rigby—a daughter.
WRIGHT.—On Jan. 24, in London, the wife of Captain John T. Wright, R.A.V.C.—a son.

MARRIAGES

HARWOOD—HUGHES-JONES.—On [illegible] London, Robert Paul Harwood, M.R.C.S., R.A.M.[illegible] er,
KEYMER—GRAY.—On Jan. 23, at [illegible] O.B.E., to Mary Rae Gray, M.B.
PALMER—SMYTH-RICHARDS.—On Jan. 21, at West Buckland, Devon, G. R. C. Palmer, M.R.C.S., lieut.-colonel I.M.S., to Mary Smyth-Richards.

DEATHS

AYLWARD.—On Jan. 29, at Tunbridge Wells, Walter Charles Aylward, M.R.C.S., aged 89.
FIDO.—On Jan. 25, in London, Herbert Adamson Fido, M.R.C.S., aged 81.
LAMBERT.—On Jan. 26, at Bucklebury, Berks, Gordon Ormsby Lambert, M.D. Camb., F.R.C.P.
LANKESTER.—On Jan. 30, at Eastbourne, Herbert Henry Lankester, M.D. Lond., aged 84.
MACLEOD.—On Jan. 24, at Bradford, Norman Alexander Macleod, M.D. Glasg.
MOORE.—On Jan. 26, Reginald Mark Moore, M.B. Camb.
SMITH.—On Jan. 30, at Long Eaton, Notts, Reginald Farmery Smith, M.R.C.S.
WHITFIELD.—On Jan. 31, at Eastbourne, Arthur Whitfield, M.D. Lond., F.R.C.P., aged 78.
WRIGHT.—On Jan. 25, at Romford, Essex, Samuel Reginald Wright, M.R.C.S., aged 78.

The first issue of the *Nutrition Bulletin* contains articles on the consumption of milk, the meat ration, school meals, and food education. The bulletin, which is intended for those interested in the application of nutritional knowledge to social welfare and public health, will be issued every two months by the Central Council for Health Education, Tavistock House, Tavistock Square, London, W.C.1. The annual subscription is 3s.

The Ministry of Food bulletin, *Food and Nutrition,* now appears in a new and improved form. This little journal, hitherto hampered by paper restrictions, has proved so popular that it is now to be printed by H.M. Stationery Office, and will be accessible to a wider circle of readers. It appears monthly at a subscription rate of 4s. yearly, and records advances in our knowledge of foods, encourages the study of food values, and answers questions.

He found that 79% of the instances of agranulocytosis occurred between the fourth and eighth weeks after starting treatment. After the second month of treatment, therefore, the period of greatest danger, both from agranulocytosis and from the less alarming complications, can be regarded as past.

As regards the complications after thyroidectomy, most of the cases of tetany were mild and cleared quickly; some of them might easily have been missed if the condition had not been specifically looked for. Similarly, the vocal cords were examined before and after operation as a routine, and it was noted that in some cases a unilateral cord palsy produced only the slightest alteration in function. Postoperative auricular fibrillation usually ceased spontaneously in forty-eight hours and did not lead to cardiac failure.

The incidence of myxœdema is roughly the same in the two series. This suggests that the "antithyroid potency" of the two agents—thyroidectomy and thiouracil—is of roughly the same order. From the practical point of view, however, there is a difference, for the symptoms and signs of thiouracil-induced myxœdema disappear rapidly when the dose is reduced, *whereas surgically induced myxœdema is for the most part permanent*, though easily controlled by thyroid extract.

IMMEDIATE RESULTS

The effects of thyroidectomy and of thiouracil on the minimal waking pulse-rate and on the basal metabolic rate (B.M.R.) in the initial period were as follows:

	THYROIDECTOMY SERIES *Mean*	THYROIDECTOMY SERIES *S.D.*	THIOURACIL SERIES *Mean*	THIOURACIL SERIES *S.D.*
Minimum waking pulse-rate per min.:				
Initial ..	96·3	12·1	99·4	20·0
Final ..	76·3	6·24	84·0	11·2
B.M.R.:				
Initial ..	+19·6%	20·2	+42·6%	14·2
Final ..	−0·7%	15·7	+10·0%	12·0

The figures given above refer to the period in hospital, generally comprising about four weeks in either case; the period from the time of operation to the time of discharge was only about two weeks, and therefore shorter than the period from the start of thiouracil treatment to the time of discharge from hospital.

Sleeping pulse-rates were not as a rule recorded postoperatively; therefore only waking pulse-rates are compared. These show a greater fall in the surgical series. A similar effect is shown with the B.M.R. figures; *but these should be interpreted with caution*, since postoperative estimations were done on only 17 cases.

The surgical patients were not weighed as a routine before leaving hospital, so we cannot compare the changes in weight in the two series. From what figures we have it seems that there is no gain in weight in the first two weeks after operation (the non-specific tendency of any operation to cause a negative nitrogen balance may have been a factor); whereas the thiouracil series gained on an average 6 lb. while in hospital.

Though 9 cases with auricular fibrillation were treated with thiouracil, it was used only as a preoperative measure in 3 of them. Of the remaining 6, 2 patients developed drug-reactions, and thiouracil was discontinued after two and six weeks; fibrillation was still present at that time. Of the remaining 4 patients, 2 had gross arteriosclerotic heart disease; one of these subsequently died of coronary thrombosis, and the other became regular on thiouracil but developed fibrillation again twelve months later. There remain therefore only 2 cases in which the action of thiouracil on fibrillation could be studied. In one of these the heart became regular three weeks after the start of thiouracil therapy; in the other the heart *did not revert to normal rhythm* until quinidine was given in addition. Normal rhythm has continued in both. It will be seen that for a variety of reasons there are not sufficient uncomplicated cases for a fair comparison of the effects of thyroidectomy and thiouracil in thyrotoxicosis with auricular fibrillation.

We conclude that with both types of treatment there was evidence of a considerable amelioration by the time the patient left hospital, *and that possibly this was* greater in the surgical series.

LATER RESULTS

When the patient has left hospital the comparison of results becomes more difficult. For the purposes of general comparison we feel that the best index is the proportion of cases which are both subjectively and objectively free of symptoms of thyrotoxicosis. For this reason we have classified as "apparently cured" those patients who are leading a normal life, free of symptoms (excluding those who admit on questioning to "slight palpitations"), and whose resting (outpatient) pulse-rates are 80 or less per min. Patients who fulfil these requirements *can fairly be considered free* of their thyrotoxicosis. The use of a strict criterion such as this does injustice to any form of treatment, for in both of the present series the proportion of patients who are satisfied with the result is certainly higher than the proportion of those "apparently cured." The latter is therefore to be taken as an index of the effectiveness of a treatment and not as an estimate of the number of cases that can be expected to benefit by it. The results at intervals of three or six months are shown in table II.

TABLE II—GENERAL COMPARISON OF THE EFFECTS OF THYROIDECTOMY AND THIOURACIL

Months after start of treatment	*Thyroidectomy series*		*Thiouracil series*	
	No. of cases	Percentage "apparently cured"	No. of cases	Percentage "apparently cured"
3	87	*20*	69	*32*
6	82	*36*	57	*35*
12	82	*29*	48	*37*
18	85	*32*	31	*45*
24	56	*30*	20	*40*
30	68	*38*	12	*42*

We cannot present any numerical data concerning the time after start of treatment at which patients returned to work. Most of our patients were engaged in housework after leaving hospital, and they progressively increased the amount of work done during the day, so it is impossible to state a definite time at which their work-capacity became normal. So far as we have been able to judge, nearly all cases, of either sex, resumed their usual occupations within a month after leaving hospital.

The figure shows the rate of gain of weight in the two series, the patient's initial weight being taken as the starting-point. Since this figure was obtained in hospital, without outdoor clothes, the gain of weight shown for the first period is over-estimated in both series.

In our observations on eye signs we have distinguished between retraction of the upper eyelids (*lid-retraction*) and true proptosis (exophthalmos). Proptosis does not appear to be directly related to the degree of thyrotoxicosis and was not materially affected by treatment in either series. Lid-retraction, which seems to have a more direct relation to thyrotoxicosis, tended to decline after both thyroidectomy and thiouracil. The time taken for lid-retraction to disappear in 55 cases treated by thyroidectomy and 49 cases treated with thiouracil was as follows:

Months after start of treatment	*Percentage of cases with lid-retraction* *Thyroidectomy*	*Thiouracil*
0	100	100
3	66	89
6	63	69
12	47	65
18	38	35

During the first twelve months the rate of decline was greater in the thyroidectomy series, but at eighteen months lid-retraction had disappeared in about the same proportion in both series.

Apart from lid-retraction, it seems that symptoms disappear at about the same rate whether patients are treated with thiouracil or by thyroidectomy. The methods of measurement used do not permit of fine distinctions, and we do not consider that the data presented here indicate more than that thyroidectomy and thiouracil are of the same order of effectiveness.

Most of the patients treated with thiouracil still have a goitre. Whether such a persistent goitre is preferable to a thyroidectomy scar or not remains a matter for debate; a great deal depends on the quality of the scar, which in some cases may be almost invisible but in others may be extremely ugly. In 8 of our thiouracil cases an initially large goitre has become impalpable, or palpable only with difficulty. On the other hand, the 5 cases which have shown signs of myxœdema have simultaneously developed an enlargement of their goitres; when the dose of thiouracil was reduced the signs of myxœdema disappeared and the goitres reverted to their original sizes.

REMISSIONS AFTER THIOURACIL

In 25 cases which had shown a good response to thiouracil treatment was suspended, and the patients were kept under observation. In 3 cases thiouracil had been administered for six months or less, in 9 cases for twelve months, in 7 cases for eighteen months, and in 6 cases for twenty-four to thirty months.

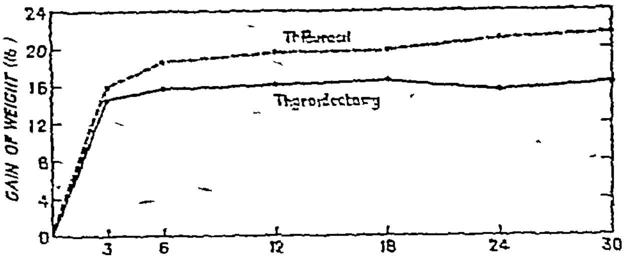
In 7 of the 25 cases symptoms and signs of thyrotoxicosis have recurred and thiouracil has had to be started again. Of these relapses, 1 occurred six months after the treatment was stopped; 2 occurred twelve months, and 4 between eighteen and thirty months after stopping treatment. There is thus a variable latent interval before the symptoms recur, and the true relapse-rate cannot be determined until the cases have been followed for a longer period. Only 6 cases have so far been observed for eighteen months or more after treatment was stopped, and 4 of these have relapsed. It cannot yet be said with confidence that thiouracil can induce permanent remissions of thyrotoxicosis.

The duration of thiouracil therapy may have some bearing on the subsequent relapse-rate, after treatment is stopped. Thus all 7 of our relapses occurred in the 12 patients who had been treated for twelve months or less, whereas none have so far occurred in the 13 patients whose course of thiouracil was longer than twelve months. The small number of cases and the variable periods of observation do not permit of a firm conclusion on this point; but we are sufficiently impressed by our findings to suggest that, when long-term treatment with thiouracil is used, it should be continued for at least twelve months, however good the response has been.

DISCUSSION

From the data presented here the following comparisons may be drawn between long-term thiouracil therapy and thyroidectomy: (1) thiouracil therapy is applicable to roughly the same proportion of cases of toxic goitre as would be operated on by the average surgeon; (2) the death-rate with thiouracil is probably less than that of thyroidectomy in the hands of the average surgeon, and the incidence of other complications is not notably greater than after thyroidectomy; (3) the immediate effect of thiouracil on thyrotoxic symptoms is well marked though probably not so rapid as that of thyroidectomy; and (4) the long-term effects of the two types of treatment are not significantly different.

We consider that these findings justify the provisional use of thiouracil as a long-term treatment of toxic goitre.



Average gains of weight after thyroidectomy (93 cases), and after thiouracil (65 cases).

All patients with toxic goitre can be treated in this way except those with signs of tracheal compression, those with severe drug-reactions, and those who cannot be seen at regular intervals. The initial dosage used in the present series (600 mg. daily of methyl-thiouracil for three weeks) may be unnecessarily high, for in the average case of toxic goitre the speed with which the symptoms are brought under control is not of great importance. We are considering a trial of smaller doses but as yet have no experience to offer.

In the present series white-cell counts were performed weekly while the patient was in hospital and at every subsequent attendance (at intervals of two to four weeks). We do not recommend this practice for general adoption, for two reasons: first, because the only major catastrophe to be feared—agranulocytosis—develops with such suddenness that these relatively infrequent blood-counts are little safeguard; secondly, because reliance on routine blood-counts tends to produce a sense of false security and diverts attention from the only real protection. This is, that every patient should be told that if he develops a sore throat or fever he must immediately discontinue the thiouracil and report to the doctor. It is the doctor's duty, on seeing such a case, to arrange for an immediate blood-count; if this shows a severe leucopenia, treatment with penicillin and other agents is urgently required.

SUMMARY

A total of 65 cases of toxic goitre have been treated throughout with the thiouracil series of drugs. The cases have been followed for periods of up to thirty months and compared with a similar series of 93 cases treated by subtotal thyroidectomy.

The reduction in pulse-rate and B.M.R. during the first three weeks of treatment with thiouracil was similar to, but probably of lesser degree than, that produced by thyroidectomy in the same period.

From three to thirty months after the start of treatment there was no appreciable difference in the condition of the patients treated with thiouracil and those treated by subtotal thyroidectomy.

Since the mortality from thiouracil is less than the overall mortality from subtotal thyroidectomy, the continued use of this series of drugs appears to be a good alternative treatment of toxic goitre.

Thyroidectomy is, however, advisable when tracheal obstruction is present, when a drug-reaction occurs, and when the patient is unable or unwilling to attend regularly for review for an indefinite period.

In 25 cases the administration of thiouracil was stopped after from three to thirty months' treatment, and 7 cases relapsed, but no relapse has so far occurred in the 13 patients who had been under treatment for a year or longer. But in the group as a whole the longer patients were followed after the cessation of treatment the more frequently did relapse occur, and it is impossible as yet to say whether such remissions can be permanent.

We wish to thank the physicians and surgeons of University College Hospital for their generous coöperation.

MARASMUS RESEARCH TEAM, INDIA COMMAND

IN a previous report the clinical condition of Indian prisoners-of-war evacuated from Japanese prison camps was described (Walters et al. 1947). From a selected group of these patients further information has been obtained about the plasma and total circulating volume. It has generally been assumed that in malnutrition the blood and plasma volumes are decreased, but the exact extent of the fall, so far as is known, has never before been measured, nor has the rate or pattern of recovery been observed.

METHODS

Hæmoglobin (Hb) was estimated by the acid-hæmatin method with an Adams diluting-type hæmoglobinometer with a Sahli-Adams square-sectioned diluting tube. The instrument, including the one pipette used throughout, was calibrated by the alkaline-hæmatin method of Clegg and King (1942) from two separate specimens of hæmin, one from Prof. E. J. King, of the British Postgraduate Medical School, and one from Major M. Hynes, R.A.M.C., of the G.H.Q. (India) Anæmia Research Team. The two specimens gave identical results.

Red blood cells were enumerated in a Spencer "bright-line" counting chamber with an "improved Neubauer" ruling. The dilution was made in each of two calibrated pipettes, and two counts were done on each dilution. The recorded result was the average of the four counts done on every specimen of blood.

The *hæmatocrit* was done in a Wintrobe tube, the Wintrobe oxalate mixture being used as an anticoagulant. The tubes were spun at 2500 r.p.m. for 1 hour.

The *serum-protein* level was measured by the copper-sulphate specific-gravity method of Phillips et al. (1945). There is now ample evidence (see, for example, Hoch and Marrack 1945) to show that this method is reliable, and repeated checks with the micro-Kjeldahl and biuret methods have confirmed this. When unusually low figures were obtained, the results were checked chemically. All determinations were made on serum, and the relation

$$Pr = 343\ (G_p - 1{\cdot}0070)$$

was used throughout, where Pr = serum-protein concentration in g./100 ml., and G_p = serum specific gravity. This relation was found to be correct for the low serum-protein figures found in patients with malnutrition, but gave results up to 5% too low in normal and recovered patients. For convenience, however, all results have been expressed in terms of this relation.

The *albumin/globulin ratio* was measured by the biuret method, half-saturated ammonium sulphate being used as a precipitating reagent, and checked by the micro-Kjeldahl method using 22% sodium sulphate.

Surface area was calculated from body-weight and height by the Du Bois formula.

Plasma volume was measured by the Evans blue technique. The colour matching was done on diluted plasma without any previous removal of proteins with an improved form of the pocket photometer described by King and Delory (1944). This instrument, using an Ilford spectrum-orange light-filter, is well suited to plasma-volume determinations, and it is felt that such errors as arose were physiological rather than technical. Samples were withdrawn 10, 20, and 50 min. after injection of the dye, and the plasma volume at zero time was determined graphically.

Blood-volume was determined from the plasma volume and the hæmatocrit. It is assumed that the peripheral hæmatocrit gives a true estimate of the red-cell plasma ratio for the whole circulation—i.e., (1) that there are no large stores of non-circulating red cells, and (2) that there is no great quantity of plasma in cell-free films in the small vessels of the peripheral circulation. Errors caused by the invalidity of these two assumptions are in the opposite sense and tend to cancel each other. With regard to assumption (1), Ebert and Stead (1941) could find no evidence of red-cell stores in man. If assumption (2) is incorrect, the blood-volume measured would be too high, because the estimate of the red-cell volume from the plasma volume and hæmatocrit would be too high.

Preliminary measurements with the differential agglutination method (McMichael et al. 1943) and with the carbon-monoxide method (Hopper et al. 1944) indicate that there is little difference between the dye method and the more direct methods of determining red-cell volume. On the other hand, the radioactive iron method of Hahn et al. (1942) and the radioactive phosphorus method of Hevesy et al. (1944) indicate that blood-volumes measured by the dye method are some 10% too high. If this were so, the data given for the total circulating Hb and total circulating red cells would be too high, but the relative values would be of the same order and the general conclusions still valid.

Total circulating plasma protein was calculated by multiplying the plasma volume by the serum-protein concentration. This is really a measure of the total circulating serum protein —i.e., total circulating plasma protein less fibrinogen.

EXPERIMENTAL

Blood-volume measurements were made on the patients soon after they were admitted to hospital and thereafter at intervals of 3 or 4 weeks. The data obtained on admission and shortly before discharge are summarised in tables I–VI. Full details for each case have been given in an unpublished report (Walters et al. 1946), a copy of which has been deposited with the Medical Research Council. Tables I–VI also contain the results from a control series of apparently healthy Indians and those from a small series of patients studied shortly after their admission to hospital but not followed up. All the figures, for purposes of comparison, have been referred to unit body-weight, unit surface area, and unit body-height.

Tables I–VI show that, after a period of treatment in hospital, the patients approached normal in every respect; but, because the intermediate values are not given, they do not show the rate at which recovery took place, nor the relative rate of recovery of each of the different blood constituents. For instance, the plasma volume returned to normal very quickly (0–4 weeks); this was followed by the blood-volume and total circulating plasma protein (2–12 weeks), and it was not until much later (8–16 weeks) that such factors as the body-weight, the total circulating hæmoglobin, the concentration of Hb and plasma protein in the peripheral blood, and the albumin/globulin ratio returned to normal. Various details of this recovery process will be mentioned in the text and illustrated by individual cases. Since the phases of recovery differ considerably from patient to patient

TABLE I—HÆMATOLOGICAL FINDINGS

Group	No. of cases	Mean Hb concentration (g./100 ml.) (±S.D.)	Mean red-cell concentration (10^6 cells/c.mm.) (±S.D.)	Mean hæmatocrit (%) (±S.D.)	Mean M.C.V. (c.μ) (±S.D.)	Mean M.C.H. (γγ) (±S.D.)	Mean M.C.H.C. (%) (±S.D.)
Control series	9	15·2 ± 1·9	5·28 ± 0·48	45·5 ± 4·0	80·5 ± 8·0	29·1 ± 4·3	33·5 ± 2·4
Cases on admission	12	9·8 ± 2·0	2·52 ± 0·39	30·4 ± 4·8	121·1 ± 16·2	39·2 ± 8·0	32·0 ± 2·7
Same cases on discharge	12	13·6 ± 0·7	4·41 ± 0·57	41·6 ± 3·0	95·4 ± 8·7	31·3 ± 3·5	32·8 ± 1·9
Cases on admission not followed up	5	7·3 ± 3·1	1·93 ± 0·82	23·5 ± 10·3	121·4 ± 12·8	38·2 ± 4·5	31·5 ± 1·8

in their time relations, the use of average figures would tend to flatten and conceal the points it is desired to emphasise.

Hæmatological Findings.—The hæmatological findings in this series (table I) differed in no essential respects from those of the larger series previously reported (Walters et al. 1947). There was a normochromic macrocytic anæmia which responded well to treatment. The mean corpuscular volume (M.C.V.) and the mean corpuscular Hb (M.C.H.) fell rapidly, and the mean corpuscular Hb concentration (M.C.H.C.) remained within normal limits throughout. It was noticed, however, that the Hb concentration, the hæmatocrit, and, more rarely, the red-cell concentration usually continued to fall for a period of up to 4 weeks and then rose steadily to normal values. Two typical cases are illustrated in fig. 1.

Serum Proteins.—The serum-protein findings (table II) were also similar to those of the larger series previously reported (Walters et al. 1947). The serum-total-protein concentration was low, the reduction being confined to the albumin fraction. During treatment the serum-albumin concentration progressively rose parallel to the total-protein concentration, and the albumin/globulin ratio consequently increased. But, before increasing, the serum-total-protein concentration, like the Hb concentration, often decreased for a short time. It then returned to normal, rapidly at first, but later more slowly. It was during this period of reduced plasma-protein concentration that the delayed œdema, seen in patients recovering from protein deprivation (Stapleton 1946, Walters et al. 1947), manifested itself.

TABLE II—PLASMA PROTEIN AND PHYSICAL MEASUREMENT FINDINGS

Group	No. of cases	Mean serum protein (g./100 ml.) (±S.D.)	Mean serum albumin (g./100 ml.) (±S.D.)	Mean serum globulin (g./100 ml.) (±S.D.)	Mean ratio A./G. (x : 1) (±S.D.)	Mean body-weight (kg.) (±S.D.)	Mean height (cm.) (±S.D.)	Mean surface area (sq. m.) (±S.D.)
Control series	9	6·89 ± 0·35	4·59 ± 0·49	2·30 ± 0·30	2·0 ± 0·5	54·8 ± 5·2	165 ± 6	1·59 ± 0·10
Cases on admission	12	5·24 ± 0·74	2·63 ± 0·77	2·61 ± 0·72	1·1 ± 0·5	45·8 ± 4·1	169 ± 7	1·50 ± 0·10
Same cases on discharge	12	6·69 ± 0·42	4·25 ± 0·49	2·44 ± 0·42	1·8 ± 0·4	61·7 ± 5·7	169 ± 7	1·71 ± 0·12
Cases on admission not followed up	5	4·82 ± 0·65	3·01 ± 0·45	1·81 ± 0·35	1·7 ± 0·3	44·2 ± 5·8	166 ± 3	1·45 ± 0·08

Body-weight.—It was obvious that the body-weight of the patients studied was much below normal. The average weight on admission was 45·8 kg. (table II). This had risen, after a stay in hospital of about three months, to 61·7 kg., an increase of almost 16 kg. (over 2½ stone). The average weight on discharge (61·7 kg.) is greater than the average weight (54·8 kg.) of the control group, even when allowance is made for the difference in average height. The average reduction in weight was to 75% of the original weight. This figure, however, is misleading. Many of the patients were grossly œdematous on admission, and during the first four weeks in hospital, as the œdema disappeared, the body-weight fell; hence the reduction in body tissue other than water was much more than 25%. When the body-weight eventually began to rise, the increase was exceedingly rapid, often being some 7 lb. a week.

Body-height.—The average body-height of the patients was 169 cm. (table II). This is higher than that of the control group (165 cm.). The patients studied had obviously been, therefore, men of fine physique before they were imprisoned.

TABLE III—PLASMA VOLUME AND BLOOD-VOLUME FINDINGS

Group	No. of cases	Mean plasma volume (ml.) (±S.D.)	Mean plasma volume per kg. (ml./kg.) (±S.D.)	Mean plasma volume per sq. m. (ml./sq. m.) (±S.D.)	Mean plasma volume per cm. (ml./cm.) (±S.D.)	Mean blood-volume (ml.) (±S.D.)	Mean blood-volume per kg. (ml./kg.) (±S.D.)	Mean blood-volume per sq. m. (ml./sq. m.) (±S.D.)	Mean blood-volume per cm. (ml./cm.) (±S.D.)
Control series	9	2600 ± 229	47·5 ± 2·9	1634 ± 95	15·7 ± 1·2	4779 ± 370	86·5 ± 4·8	3004 ± 131	29·0 ± 1·7
Cases on admission	12	2446 ± 328	53·6 ± 6·2	1625 ± 182	14·4 ± 1·7	3514 ± 413	76·9 ± 7·4	2334 ± 212	20·7 ± 2·0
Same cases on discharge	12	2977 ± 458	48·1 ± 5·0	1737 ± 94	17·6 ± 2·3	5090 ± 669	82·5 ± 7·0	2973 ± 288	30·0 ± 3·4
Cases on admission not followed up	5	2430 ± 453	56·1 ± 8·1	1670 ± 244	14·6 ± 2·5	3158 ± 232	73·9 ± 10·9	2186 ± 168	19·0 ± 1·0

Surface Area.—This was calculated from the body-weight and height by the Du Bois formula. The area, so calculated, was low on admission and, during treatment, it at first fell slightly and then returned slowly to normal (table II).

Plasma Volume (table III).—The mean plasma volume of the patients on admission to hospital was 2446 ml., which is slightly lower than that of the control group (2600 ml.); but the difference is of doubtful significance. The mean figure is also less than that reported by Mollison (1946) for patients in Belsen Camp, but the scatter, 1880 ml.–2940 ml., covers much the same range. If the plasma volume were originally low, it increased to normal quickly (0–4 weeks), and then rose to well above the normal figure (2–12 weeks); and it was only later (8–16 weeks) that it fell again to normal levels. In all the cases studied the plasma volume was the first figure to return to normal.

The plasma volume referred to the body-weight in kilogrammes (PV/kg.) was above normal when the patients were admitted to hospital. This means that the relative decrease in plasma volume was not as great as that of the body-weight. During recovery PV/kg. invariably rose to figures far in excess of normal and then gradually fell again to normal values. This is because, during the early weeks of recovery, the plasma volume increased much more rapidly than the body-weight; the plasma volume reached normal values after 0–4 weeks, but the body-weight not until 8–16 weeks.

TABLE IV—TOTAL CIRCULATING HÆMOGLOBIN FINDINGS

Group	No of cases	Mean Hb concentration (g./100 ml.) (±S.D.)	Mean total circulating Hb (g.) (±S.D.)	Mean total circulating Hb per kg. (g./kg.) (±S.D.)	Mean total circulating Hb per sq. m. (g./sq. m.) (±S.D.)	Mean total circulating Hb per cm. (g./cm.) (±S.D.)
Control series	9	15·2 ± 1·9	730 ± 117	13·4 ± 2·5	460 ± 71	4·4 ± 0·7
Cases on admission	12	9·8 ± 2·0	345 ± 79	7·5 ± 1·7	229 ± 50	2·0 ± 0·4
Same cases on discharge	12	13·6 ± 0·7	692 ± 55	11·2 ± 1·1	405 ± 39	4·1 ± 0·4
Cases on admission not followed up	5	7·3 ± 3·1	225 ± 87	5·5 ± 2·6	159 ± 67	1·3 ± 0·5

MARASMUS RESEARCH TEAM, INDIA COMMAND

IN a previous report the clinical condition of Indian prisoners-of-war evacuated from Japanese prison camps was described (Walters et al. 1947). From a selected group of these patients further information has been obtained about the plasma and total circulating volume. It has generally been assumed that in malnutrition the blood and plasma volumes are decreased, but the exact extent of the fall, so far as is known, has never before been measured, nor has the rate or pattern of recovery been observed.

METHODS

Hæmoglobin (Hb) was estimated by the acid-hæmatin method with an Adams diluting-type hæmoglobinometer with a Sahli-Adams square-sectioned diluting tube. The instrument, including the one pipette used throughout, was calibrated by the alkaline-hæmatin method of Clegg and King (1942) from two separate specimens of hæmin, one from Prof. E. J. King, of the British Postgraduate Medical School, and one from Major M. Hynes, R.A.M.C., of the G.H.Q. (India) Anæmia Research Team. The two specimens gave identical results.

Red blood cells were enumerated in a Spencer "bright-line" counting chamber with an "improved Neubauer" ruling. The dilution was made in each of two calibrated pipettes, and two counts were done on each dilution. The recorded result was the average of the four counts done on every specimen of blood.

The *hæmatocrit* was done in a Wintrobe tube, the Wintrobe oxalate mixture being used as an anticoagulant. The tubes were spun at 2500 r.p.m. for 1 hour.

The *serum-protein* level was measured by the copper-sulphate specific-gravity method of Phillips et al. (1945). There is now ample evidence (see, for example, Hoch and Marrack 1945) to show that this method is reliable, and repeated checks with the micro-Kjeldahl and biuret methods have confirmed this. When unusually low figures were obtained, the results were checked chemically. All determinations were made on serum, and the relation

$$Pr = 343\ (G_p - 1{\cdot}0070)$$

was used throughout, where Pr = serum-protein concentration in g./100 ml., and G_p = serum specific gravity. This relation was found to be correct for the low serum-protein figures found in patients with malnutrition, but gave results up to 5% too low in normal and recovered patients. For convenience, however, all results have been expressed in terms of this relation.

The *albumin/globulin ratio* was measured by the biuret method, half-saturated ammonium sulphate being used as a precipitating reagent, and checked by the micro-Kjeldahl method using 22% sodium sulphate.

Surface area was calculated from body-weight and height by the Du Bois formula.

Plasma volume was measured by the Evans blue technique. The colour matching was done on diluted plasma without any previous removal of proteins with an improved form of the pocket photometer described by King and Delory (1944). This instrument, using an Ilford spectrum-orange light-filter, is well suited to plasma-volume determinations, and it is felt that such errors as arose were physiological rather than technical. Samples were withdrawn 10, 20, and 50 min. after injection of the dye, and the plasma volume at zero time was determined graphically.

Blood-volume was determined from the plasma volume and the hæmatocrit. It is assumed that the peripheral hæmatocrit gives a true estimate of the red-cell plasma ratio for the whole circulation—i.e., (1) that there are no large stores of non-circulating red cells, and (2) that there is no great quantity of plasma in cell-free films in the small vessels of the peripheral circulation. Errors caused by the invalidity of these two assumptions are in the opposite sense and tend to cancel each other. With regard to assumption (1), Ebert and Stead (1941) could find no evidence of red-cell stores in man. If assumption (2) is incorrect, the blood-volume measured would be too high, because the estimate of the red-cell volume from the plasma volume and hæmatocrit would be too high.

Preliminary measurements with the differential agglutination method (McMichael et al. 1943) and with the carbon-monoxide method (Hopper et al. 1944) indicate that there is little difference between the dye method and the more direct methods of determining red-cell volume. On the other hand, the radioactive iron method of Hahn et al. (1942) and the radioactive phosphorus method of Hevesy et al. (1944) indicate that blood-volumes measured by the dye method are some 10% too high. If this were so, the data given for the total circulating Hb and total circulating red cells would be too high, but the relative values would be of the same order and the general conclusions still valid.

Total circulating plasma protein was calculated by multiplying the plasma volume by the serum-protein concentration. This is really a measure of the total circulating serum protein —i.e., total circulating plasma protein less fibrinogen.

EXPERIMENTAL

Blood-volume measurements were made on the patients soon after they were admitted to hospital and thereafter at intervals of 3 or 4 weeks. The data obtained on admission and shortly before discharge are summarised in tables I–VI. Full details for each case have been given in an unpublished report (Walters et al. 1946), a copy of which has been deposited with the Medical Research Council. Tables I–VI also contain the results from a control series of apparently healthy Indians and those from a small series of patients studied shortly after their admission to hospital but not followed up. All the figures, for purposes of comparison, have been referred to unit body-weight, unit surface area, and unit body-height.

Tables I–VI show that, after a period of treatment in hospital, the patients approached normal in every respect; but, because the intermediate values are not given, they do not show the rate at which recovery took place, nor the relative rate of recovery of each of the different blood constituents. For instance, the plasma volume returned to normal very quickly (0–4 weeks); this was followed by the blood-volume and total circulating plasma protein (2–12 weeks), and it was not until much later (8–16 weeks) that such factors as the body-weight, the total circulating hæmoglobin, the concentration of Hb and plasma protein in the peripheral blood, and the albumin/globulin ratio returned to normal. Various details of this recovery process will be mentioned in the text and illustrated by individual cases. Since the phases of recovery differ considerably from patient to patient

TABLE I—HÆMATOLOGICAL FINDINGS

Group	No. of cases	Mean Hb concentration (g./100 ml.) (±S.D.)	Mean red-cell concentration (10⁶ cells/c.mm.) (±S.D.)	Mean hæmatocrit (%) (±S.D.)	Mean M.C.V. (c.μ) (±S.D.)	Mean M.C.H. (γγ) (±S.D.)	Mean M.C.H.C. (%) (±S.D.)
Control series	9	15·2 ± 1·9	6·28 ± 0·48	45·5 ± 4·0	86·5 ± 8·0	29·1 ± 4·3	33·5 ± 2·4
Cases on admission	12	9·8 ± 2·0	2·52 ± 0·39	30·4 ± 4·8	121·4 ± 16·2	39·2 ± 8·0	32·0 ± 2·7
Same cases on discharge	12	13·6 ± 0·7	4·41 ± 0·57	41·6 ± 3·0	95·4 ± 8·7	31·3 ± 3·5	32·8 ± 1·9
Cases on admission not followed up	5	7·3 ± 3·1	1·93 ± 0·82	23·5 ± 10·3	121·4 ± 12·8	38·2 ± 4·5	31·5 ± 1·8

portional to the surface area. With treatment in hospital the total circulating Hb per sq.m. steadily returned to normal.

When referred to unit body-height, the total circulating Hb was greatly reduced. On admission to hospital the repatriated prisoners had only 2·0 g. of Hb per cm. of body-height, whereas the figure for the control group was 4·4 g. Presumably the latter figure is a fair estimate of the total circulating Hb per centimetre body-height of the patients before they were imprisoned. The actual loss of Hb to the body was therefore much greater than that indicated by the fall in the Hb concentration. With treatment in hospital the total circulating Hb per centimetre body-height gradually increased.

Total Circulating Red Cells (table v).—It has previously been seen that the red-cell concentration rarely fell during the early stages of recovery as did the Hb concentration. This is reflected in the progressive fall in the M.C.H. and the disappearance of the macrocytosis. Multiplying the red-cell concentration by the blood-volume gives the total number of red cells in the circulation. The average for the repatriated prisoners on admission to hospital was $8\cdot8 \times 10^{12}$ cells, whereas the figure for the control series was $25\cdot3 \times 10^{12}$, and that for the patients on discharge was $22\cdot2 \times 10^{12}$. The total number of circulating red cells thus approached normal during the period of treatment in hospital.

The total number of circulating red cells referred both to unit body-weight and unit surface area was also greatly reduced, as also was the total number of circulating red cells referred to unit body-height. The figure of $5\cdot2 \times 10^{10}$ cells/cm. on admission can be compared with $15\cdot3 \times 10^{10}$ cells/cm. for the control series. All these figures approached normal after the treatment in hospital.

Total Circulating Plasma Protein (table vi).—After a period during which there was little improvement, the serum-protein concentration rose, at first rapidly and then more slowly, until normal values were reached. This rise was almost entirely in the albumin fraction; hence there was a progressive increase in the albumin/globulin ratio. By multiplying the serum-protein concentration by the plasma volume, an estimate is obtained of the total circulating plasma protein. It is seen that this was 128 g. when the patients were admitted to hospital, compared with 199 g. when they were discharged and 180 g. for the control group. It is also seen that, even though many of the patients were received in a state of acute protein deprivation, the relative decrease in the total circulating plasma protein was less than that of the total circulating Hb, because the relative reduction of the plasma volume was less than that of the blood-volume, and the relative reduction in serum-protein concentration was less than that of the Hb concentration. The improvement in the total circulating plasma protein was both dramatic and rapid. Normal figures were reached at the end of 2–12 weeks, long before normal figures for the total circulating Hb.

TABLE VII—STAGES OF RECOVERY IN PROTEIN DEFICIENCY

Observation	Stage I (0–4 weeks)	Stage II (2–12 weeks)	Stage III (8–16 weeks)
Body-weight	Decreases	Increases rapidly	Increases to normal
Plasma volume	Increases rapidly to normal	Increases rapidly to above normal	Decreases to normal
Blood-volume	Increases	Increases to normal	No change
Hb concentration and hæmatocrit	Decreases or no change	Increases	Increases to normal
Total circulating Hb	Increases	Increases rapidly	Increases to normal
Red-cell concentration	Increases slightly or no change	Increases	Increases to normal
Total circulating red cells	Increases	Increases rapidly	Increases to normal
Plasma-protein concentration	No change or increases slightly	Increases rapidly	Increases slightly to normal
Total circulating plasma protein	Increases	Increases very rapidly to normal	No change
Total circulating albumin	Increases	Increases rapidly	Increases to normal
Total circulating globulin	Increases slightly from normal	Increases to above normal	Decreases to normal
A/G. ratio	Increases slightly	Increases	Increases to normal

TABLE VIII—RATE OF PRODUCTION OF HB, RED CELLS, AND PLASMA PROTEIN

Case	Time observed (days)	Change in total circulating			Change per day in total circulating		
		Hb (g.)	Red cells (cells × 10^{12})	Plasma protein (g.)	Hb (g./day)	Red cells (cells × 10^{10}/day)	Plasma protein (g./day)
5	35	235	9·5	110	6·7	27·1	3·1
7	25	144	6·7	73	5·8	26·8	2·9
10	28	295	12·3	77	10·5	43·8	2·8
24	18	140	3·3	31	7·8	18·3	1·7
25	30	180	7·3	47	6·0	24·3	1·6
26	25	153	5·8	68	6·1	23·2	2·7
28	25	101	4·6	43	4·0	18·4	1·7
31	29	354	12·2	55	12·2	42·1	1·9
32	33	352	11·1	49	10·7	33·6	1·5
34	21	205	6·2	47	9·8	29·5	2·2
36	25	181	3·8	70	7·2	15·2	2·8
				Mean	7·9	27·2	2·3

The total circulating plasma protein increased steadily in all cases, even though, in many, the serum-protein concentration fell at first. The initial rise in plasma volume was so rapid that there was always an increase in total circulating plasma protein. Fig. 3 illustrates these particular points in two typical cases. As in the case of the Hb, it does not necessarily follow that, because the serum-protein concentration falls, the patient is not progressing. In patient 28 (fig. 3) plasma protein was being produced at the rate of 12 g./week, and yet the serum-protein concentration actually fell.

The total circulating plasma protein referred to unit body-weight (Pr/kg.) was slightly less than that of the control series, indicating that plasma protein was not greatly reduced relative to other tissues. Because of the rapid rise in total circulating plasma protein and the slower rise in body-weight, Pr/kg. quickly rose to figures well above normal before it fell again to normal levels. The total circulating plasma protein referred to both unit surface area and unit body-height was also reduced, and in both cases rose very rapidly to normal values.

It is seen that the reduction in the total circulating plasma protein was entirely in the albumin fraction. The total circulating albumin was only 50% of normal, whereas there was no change in the total circulating globulin. On recovery, at first both fractions increased, but the albumin increased more rapidly than the globulin. Then, as time progressed, the increase in total circulating albumin became more rapid, and that of total circulating globulin less rapid, until finally, in many cases, the total circulating globulin, which by now had

The plasma volume referred to unit surface area (PV/sq.m.) was much more constant. It was within normal limits when the patients were admitted to hospital and remained so when they were discharged. During the initial recovery phase (0–4 weeks) it rose slightly on occasions, but the percentage rise was small compared with that of PV/kg.

The plasma volume referred to unit body-height (PV/cm.) was low on admission, 14·4 ml./cm. compared with 17·6 ml./cm. for the same patients on discharge and 15·7 ml./cm. for the control series. Like the absolute plasma volume, PV/cm. first rapidly increased to above normal and then decreased to normal values.

Blood-volume (table III).—The mean total circulating volume of 3514 ml., observed when the patients were admitted to hospital, was considerably lower than either that of the control series, 4779 ml., or that of the same patients on discharge, 5090 ml. This mean figure is of the same order as that reported by Mollison (1946) for the Belsen cases. The low total circulating volume gradually returned to normal (2–12 weeks). This return to normal was *not so rapid as that of the plasma volume (0–4 weeks)*, but it was much quicker than the return to normal of many of the other factors measured. Unlike the plasma volume, there was not a period when the figures for the total circulating volume were greatly in excess of normal.

The blood-volume, even when referred to unit body-weight (BV/kg.), was on the average lower than normal (76·9 ml./kg. on admission, compared with 82·5 ml./kg. on discharge and 86·5 ml./kg. for the control series). Mollison (1946), quoting normal values of Gibson and Evans (1937), states that "blood-volume in severely undernourished subjects is not reduced in proportion to body-weight." In 10 out of the 12 of our cases so studied, BV/kg. on admission was less than that on discharge, and in 15 out of the total of 17 patients BV/kg. on admission was lower than the mean of the control group, all the estimations being done by exactly the same technique. Application of Fisher's "t" test gives: P is less than 0·01 for the difference between the means of the patients on admission and those of the control group, and P is less than 0·02 for the difference between the means of the patients of cases investigated on admission but not followed up and the control group. It therefore seems clear that the total circulating volume is decreased to a slightly greater extent than the other body tissues. BV/kg. returned to normal after first going through a period when it was above normal. This was due to the fact that, on recovery, the total circulating volume increased more rapidly than the body-weight.

The blood-volume referred to unit surface area (BV/sq.m.) was reduced relatively much more than BV/kg. During treatment BV/sq.m. rose steadily to normal values. The relative reduction in blood-volume referred to unit body-height (BV/cm.) was greater still. A normal Indian (control series) has 29·0 ml. of blood for every cm. of his body-height, but the repatriated prisoner, on admission to hospital, had only 20·7 ml., whereas on discharge he had 30·0 ml. Improvement of BV/cm. was continuous throughout the whole of the recovery period.

TABLE V—TOTAL CIRCULATING RED-CELL FINDINGS

Group	No. of cases	Mean red-cell concentration (10^{6} cells/c.mm.) (±S.D.)	Mean total circulating red cells (cells × 10^{12}) (±S.D.)	Mean total circulating red cells per kg. (cells × 10^{10}/kg.) (±S.D.)	Mean total circulating red cells per sq.m. (cells × 10^{12}/sq.m.) (±S.D.)	Mean total circulating red cells per cm. (cells × 10^{10}/cm.) (±S.D.)
Control series	9	5·28 ± 0·48	25·3 ± 3·7	46 ± 4	15·9 ± 1·7	15·3 ± 2·0
Cases on admission	12	2·52 ± 0·39	8·8 ± 1·4	19 ± 3	5·9 ± 0·9	6·2 ± 0·8
Same cases on discharge	12	4·41 ± 0·57	22·2 ± 2·6	36 ± 5	13·1 ± 1·7	13·1 ± 1·6
Cases on admission not followed up	5	1·93 ± 0·82	6·0 ± 2·5	15 ± 8	4·3 ± 2·0	3·7 ± 1·5

Total Circulating Hb (table IV).—It has previously been seen that in the early stages of recovery there was often a phase during which the Hb concentration, before it began to improve, actually fell still further. If the Hb concentration is multiplied by the blood-volume, the total amount of Hb in the circulation can be calculated. It was found that the total circulating Hb rose steadily throughout the whole of the recovery period, even though in the initial stages the Hb concentration may have fallen, for it was at this time, when the Hb concentration was falling, that the increase in blood-volume was greatest. These points are well illustrated *in fig. 2, which gives the Hb concentration*, total circulating Hb, and total circulating volume changes in two typical cases. This is important from the clinical viewpoint, for it means that a patient may be producing Hb into the circulation at a surprisingly high rate—in the two cases illustrated Hb was being formed at the rate of 40·5 and 28·0 g./week—with the Hb concentration actually falling. It follows therefore that, if the Hb concentration of an undernourished patient falls during the first few weeks' treatment, *it does not necessarily* mean that the patient's condition is deteriorating. He may still be elaborating Hb at a very satisfactory rate.

TABLE VI—TOTAL CIRCULATING PLASMA-PROTEIN FINDINGS

Group	No. of cases	Mean plasma-protein concentration (g./100 ml.) (±S.D.) (*albumin + globulin*)	Mean total circulating plasma protein (g.) (±S.D.) (*albumin + globulin*)	Mean total circulating plasma protein per kg. (g./kg.) (±S.D.) (*albumin + globulin*)	Mean total circulating plasma protein per sq m. (g./sq.m.) (±S.D.) (*albumin + globulin*)	Mean total circulating plasma protein per cm. (g./cm.) (±S.D.) (*albumin + globulin*)
Control series	9	6·89 ±0·35 (*4·59 + 2·30*)	180 ±21 (*120 + 60*)	3·3 ±0·3 (*2·2 + 1·1*)	113 ±10 (*75 + 38*)	1·09 ±0·11 (*0·73 + 0·36*)
Cases on admission	12	5·24 ±0·74 (2·63 + 2·61)	128 ±33 (64 + 64)	2·8 ±0·7 (1·4 + 1·4)	85 ±20 (43 + 42)	0·75 ±0·17 (0·38 + 0·37)
Same cases on discharge	12	6·69 ±0·42 (4·25 + 2·44)	199 ±31 (125 + 74)	3·2 ±0·4 (2·0 + 1·2)	117 ±15 (74 + 43)	1·17 ±0·17 (0·74 + 0·43)
Cases on admission not followed up	5	4·82 ±0·65 (3·01 + 1·81)	120 ±34	2·7 ±0·7	82 ±22	0·72 ±0·20

The total circulating Hb when the patients were admitted to hospital was exceedingly low, 345 g. compared with 730 g. for the control series, but by the time the patients were fit for discharge it had risen to 692 g. The total circulating Hb per kg. of body-weight was also greatly decreased on admission, signifying that the loss of Hb *was relatively much greater than the* loss of other body tissues. During the period of treatment in hospital this rose rapidly at first, and then more slowly.

The relative reduction of the total circulating Hb referred to unit surface area was much greater. When the patients were admitted to hospital the total circulating Hb per sq.m. of body surface area was 229 g., compared with 405 g. for the same patients on discharge and 460 g. for the control series. This figure gives some idea of the disability under which *the patients* were suffering during their imprisonment, because the Hb requirement is pro-values far in excess of normal in stage II, back to normal and by the maintenance of the total circulating volume at normal levels. This is accompanied by a rise in the Hb concentration, red-cell concentration, and hæmatocrit, and therefore of the total circulating Hb and total circulating red cells. There is a steady rise in the body-weight and a rise in the plasma-protein concentration; but, because of the fall in plasma volume, the total circulating plasma protein remains the same. There is, however, still a rise in the total circulating albumin, which is balanced by a corresponding fall in the total circulating globulin. This is reflected in the continued increase of the albumin/globulin ratio.

The above description, which is of necessity an over-simplification, is summarised in table VII, and the salient features of the stages of recovery are represented schematically in fig. 4.

RATE OF RECOVERY

The total circulating Hb, the total circulating red cells, and the total circulating plasma protein being known at any given stage in the recovery process, it is possible to judge the rate of recovery in terms of the rate of production of Hb, red cells, or plasma protein.

Table VIII gives the change in total circulating Hb, red cells, and plasma protein in a series of patients at the time of maximal recovery. It is seen that the average rate of Hb production for the series was 7·9 g. a day (or roughly, if the total circulating volume remains constant, 1% a day on the Haldane scale). The average rate of red-cell production was 27·2 × 10^{10} cells per day. This reduces to the astonishing figure of 3 million cells every second. The average rate of plasma-protein production was 2·3 g. a day. Thus, even though every tissue of the body must be suffering from protein deprivation, over 10 g.* of the daily dietary protein intake is converted either to Hb or plasma protein. Of the 2·3 g. a day of plasma protein formed 1·5–2 g. is albumin. On the basis of the calculations of Sachar et al. (1942) this would mean a deposition of tissue protein of about 37–50 g. a day.

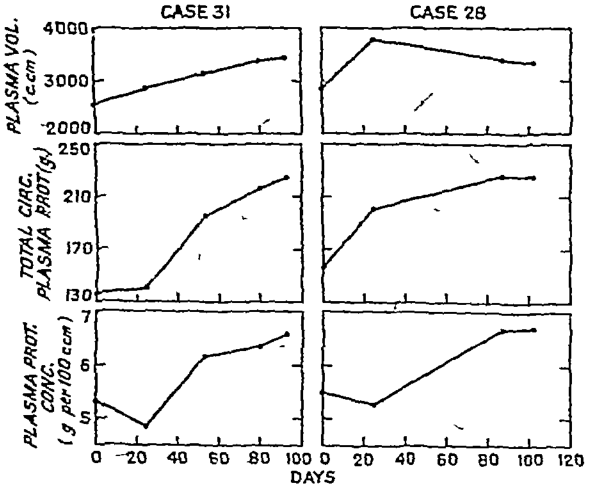

Fig. 3—Typical changes in cases 31 and 28 (see table VIII).

SUMMARY

Plasma- and blood-volume observations were made on Indian prisoners repatriated from Japanese prison camps and on a control series of apparently healthy Indians.

The chief findings in the ex-prisoners on admission to hospital were a normochromic macrocytic anæmia: a reduction in the serum-total-protein concentration which was confined almost entirely to the albumin fraction, and hence a reduction in the albumin/globulin ratio; a reduction in body-weight; little change in plasma volume; an increase in plasma volume referred to unit body-weight, no change referred to unit surface area, and a decrease referred to unit body-height; a reduction in total circulating blood-volume which was also reduced when referred to a unit body-weight, unit surface area, and unit body-height; a reduction in the total circulating Hb, total circulating red cells, and total circulating plasma protein which was also reduced when referred to unit body-weight, unit surface area, and unit body-height. The reduction in total circulating plasma protein was entirely in the globulin fraction.

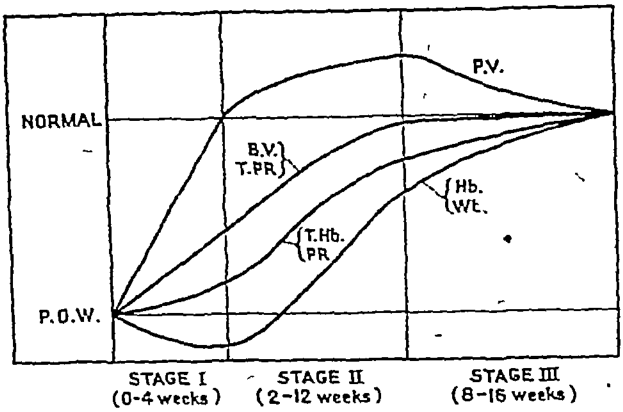

Fig. 4—Schematic representation of stages of recovery: P.V., plasma volume; B.V., blood-volume; Hb, hæmoglobin concentration; PR, plasma-protein concentration; T.PR, total circulating plasma protein; T.Hb, total circulating Hb; Wt., body-weight.

All the above findings returned to normal during treatment in hospital.

The Hb concentration, and sometimes the plasma-protein concentration, often fell during the first four weeks' treatment in hospital. Although this was so, the increase in blood and plasma volume was so great that the total circulating Hb and plasma protein was increased. Therefore it does not necessarily follow that, because the Hb concentration or serum-protein concentration falls during the initial stages of treatment, the patient is not making satisfactory progress.

The rate of recovery of each of the above factors was followed, and from this the pattern of recovery was reconstructed. The recovery process has been divided into three arbitrary stages, which have been described in detail.

The rate of recovery in terms of the rate of production of Hb, red cells, and plasma protein was also observed.

We are grateful to the Director of Medical Services, India, for permission to publish this paper.

* This is neglecting the non-Hb protein content of the packed cell volume, which may be considerable.

risen to figures above normal, began to decline. Some interest attaches to the reduction in total circulating albumin because of the finding of Sachar et al. (1942) that the reduction of tissue protein produced by an insufficient dietary intake of protein is directly proportional to the reduction of total circulating albumin. On the basis of nitrogen-loss experiments in dogs, these workers concluded that

$$T.Pr_t = 25 \times Alb_t$$

where $T.Pr_t$ and Alb_t represent the loss in g. of tissue protein and total circulating albumin respectively. The difference between the mean total circulating albumin of the prisoners on discharge and that on admission was 61 g. Application of the above formula would thus give a tissue protein loss of 1525 g.

The formula of Sachar et al. (1942) for calculating the loss of total circulating albumin,

$$Alb_t = 0{\cdot}5\ Wt\ (4{\cdot}6 - Alb_c)$$

where Wt is the normal body-weight in kg. and Alb_c is the serum-albumin concentration in g./100 ml., gives *an estimated albumin loss of 62 g. compared with the* loss of 61 g. measured directly.

When referred to unit body-weight, surface area, or body-height, the figures for the total circulating albumin and globulin do not reveal many points of special interest. It will be noticed, however, that, since the total circulating globulin was normal on admission when the body-weight was reduced, the total circulating globulin, when referred to unit body-weight, was above normal (1·4 g./kg. as opposed to 1·1 g./kg.). As the body-weight increased, the total circulating globulin per kilogramme body-weight fell.

STAGES OF RECOVERY

From the foregoing it is possible to reconstruct the general picture of the pattern of recovery in a protein-deficient patient. For the sake of ease of description this recovery process has been divided into three stages. These are arbitrary and show very considerable variations *in their time relations*. Most of the patients studied, however, demonstrated these stages clearly, and the remainder would, we feel confident, have demonstrated them had blood-volume determinations been done at sufficiently frequent intervals. It must also be remembered that, in some of the patients, the recovery process had already begun during their evacuation to India; in these, stage I had been passed before they were admitted to hospital.

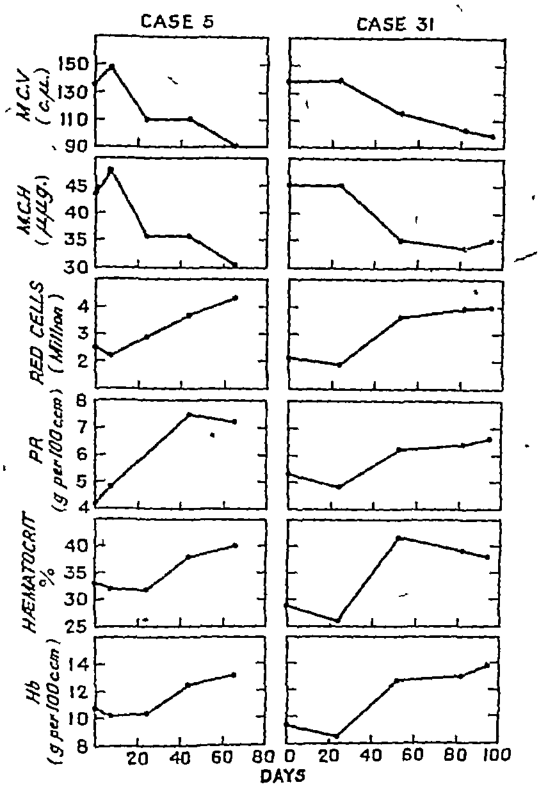

Fig. 1—Typical changes in cases 5 and 31 (see table VIII): Hb, hæmoglobin; PR, plasma-protein concentration; M.C.H., mean corpuscular Hb; M.C.V., mean corpuscular volume.

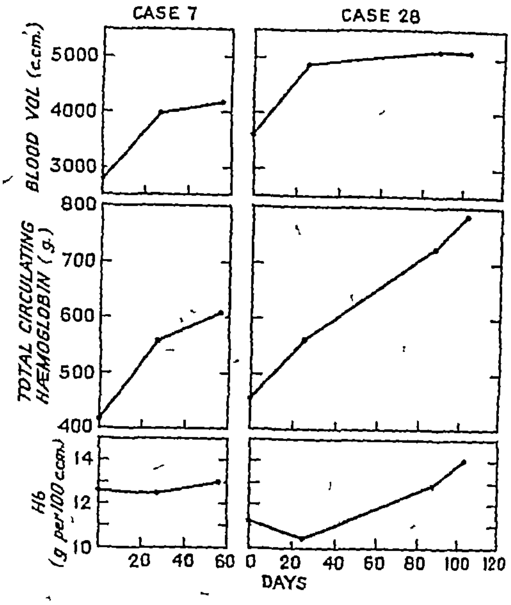

Fig. 2—Typical changes in cases 7 and 28 (see table VIII).

Stage I (0–4 weeks).—This is characterised by the rapid rise in plasma volume to normal. During this period the body-weight at first falls as œdema disappears, and then may slowly rise. The blood-volume rises steadily but at such a rate that, though the Hb concentration, together with the hæmatocrit, usually falls, the total circulating Hb increases. Despite the decrease in Hb concentration, the red-cell concentration may increase, since the M.C.H. is falling as the patient's blood is rapidly becoming less macrocytic. The number of circulating red cells increases, as does the total circulating plasma protein. Because of the rapid rise in plasma volume, the plasma-protein concentration changes but little: it sometimes falls slightly and sometimes increases. The increase in total circulating protein is in both fractions, but more albumin is formed than globulin; so the albumin/globulin ratio increases slightly.

Stage II (2–12 weeks).—This is characterised by the rapid rise of both the total circulating volume and the total circulating plasma protein to normal. The plasma volume, which had attained normal values in stage I, increases rapidly to values well above normal. There is also a rapid increase in body-weight and in total circulating Hb, because both the Hb concentration, which fell in stage I, and the blood-volume are increasing rapidly. The hæmatocrit and the red-cell concentration, and hence the total circulating red cells, are also increasing. The increase in the total circulating protein is in both fractions, but the albumin fraction increases much more rapidly than the globulin; the total circulating globulin does, however, often reach figures well in excess of normal. The albumin/globulin ratio continues to increase.

Stage III (8–16 weeks).—This stage marks the transition from stage II to normal findings. It is characterised by the return of the plasma volume, which had risen to niplegia, dysuria, and many other symptoms have m time to time been attributed to loiasis. There is, vever, little proof that these are due to infestation L. loa. Manson-Bahr (personal communication) has own a patient with a massive infection to develop ltiple cystic swellings all over the body but chiefly the arms; these finally broke down and discharged id filariæ. The dead worms may cause abscesses, but y usually become calcified.

Chronic Calabar swellings are well recognised, and may rsist for over two months. My impression is that they velop early and are only rarely seen in the later stages after the patient's return to a cold climate. They form nore or less ill-defined lesion, usually on the arm below e elbow. Little is known of their pathology, but they thought to arise from Calabar swellings which keep urring at the same site.

PATHOLOGY

The filariæ of *L. loa* differ from those of *W. bancrofti* that they wander about the body, chiefly in the nnective tissues. As a rule they do not obstruct mphatics, but sometimes they cause fairly severe mphatic œdema and elephantiasis. Several observers aintain that in hyperendemic areas they are a common use of hydrocele, varicocele, and hernia. In such eas about 10% of patients coming to operation for rnia and allied conditions have live worms in the gions exposed. In one case Chesterman (quoted by rong 1944) found forty parasites close to the cord. he adult filariæ have been found in almost every part the body, including the heart and pericardium.

A moderate enlargement of lymph-glands is a common nding in infected patients; nearly every patient with any Calabar swellings on the arms will have enlarged pitrochlear glands.

There has been much speculation about the pathology f Calabar swellings. The theories that they indicate the irth of microfilariæ or are associated with the wanderings f the adult can now have little support. Undoubtedly hey are the local anaphylactoid reaction of the host o the loa antigen, and this explanation is borne out by he fact that they have been artificially produced by he injection of a similar type of antigen obtained from *Dirofilaria immitis* into patients with loiasis (Lloyd nd Chandra 1933).

Dead filariæ usually become calcified without suppurating and then are clearly visible on radiography.

Enlargement and chronic fibrosis of the spleen have een found at necropsy, and serial sections have shown nicrofilariæ embedded in fibrous tissue surrounded by nuch cellular infiltration. Chronic malaria may be at east a partial cause of the splenic enlargement in these cases.

Loiasis undoubtedly lasts a long time. *L. loa* is said to be able to live for twenty years, and many observers say that loiasis lasts about fourteen years. Manson-Bahr (1945) records a case in which microfilariæ persisted in the blood for seventeen years.

DIAGNOSIS

A history of visiting an endemic area at some time is essential for diagnosis, since infection cannot take place without a suitable vector.

Calabar swellings are such a constant feature that the diagnosis of loiasis should hardly be considered if there have never been any. Often physical examination will be entirely negative, but the outline of a worm may be seen under the skin, or one may be seen crossing the eye. The diagnosis must be in serious doubt if the differential white-cell count is normal, for eosinophilia is present in every case at some period.

The absence of microfilariæ from the blood is no bar to the diagnosis, since they may be absent for a considerable period even in heavy infections. They should be searched for in thick blood films taken during the daytime. If present they are usually easy to find with a low-power microscope. Either a thick fresh film with overlying coverslip and no stain, or a thick dried film stained with one of the Romanowsky stains, will reveal them. By the first method they are seen to be actively motile. If there is any doubt about the diagnosis, it may be necessary to have stained films examined to differentiate the microfilariæ of *L. loa* from the harmless microfilariæ of *A. perstans*, which is commonly found in some districts of Africa and gives rise to no symptoms.

Should the diagnosis still remain in doubt, skin tests may be carried out. These consist of the intradermal injection of a filarial antigen; an extract obtained from *D. immitis* is the one most commonly used. Or a complement-fixation test may be done on the patient's serum. Both these tests are highly accurate in the diagnosis of filarial infections as a group, differentiating them from other worm infections, but they do not give positive information about the species of filaria involved.

Ease in making the diagnosis correctly is the rule rather than the exception.

TREATMENT

General Treatment.—Prophylaxis must rest on avoiding being bitten by chrysops and any other possible vectors.

There is no known cure for loiasis. A wide variety of drugs have been tried, each in turn being credited with some successes. However, careful observation has shown that, given in doses not toxic to the host, they had no effect on the adult filariæ and little if any on the microfilariæ. Those which have seemed the most hopeful are 'Anthiomaline,' stibophen, methylene-blue, and organic arsenicals.

Microfilariæ can live for a considerable time—indeed, heavily infected blood has been injected intravenously into dogs, and more than a year later the microfilariæ have been found alive in the circulation. By themselves the microfilariæ probably cause no symptoms; therefore their destruction cannot help the host but merely prevents the continuation of a reservoir for the transmission of the disease. Thus, should an effective drug be found for killing the microfilariæ, its only justifiable use can be in an endemic area where vectors are a constant source of danger to other people.

The indiscriminate use of potent drugs in treating loiasis is not only futile but often harmful. I have seen one patient with a severe agranulocytosis following the unsuccessful administration of a toxic drug.

Deep X-ray treatment, to sterilise the female parasites in the tissues, has been advocated by some, but there does not seem to be enough justification for its use in loiasis. This form of therapy appears to have more scope in *W. bancrofti* infections.

Local Treatment.—Calabar swellings do not as a rule require any treatment, but at times local soothing applications may be indicated. Chronic swellings should benefit considerably from daily massage.

Removal of the filariæ should always be attempted when they can be located in a suitable site. This can most easily be done when they are passing over the globe under the conjunctiva. The method is as follows:

> Cocaine, in the form of a 4% solution or lamellæ containing gr. 1/[illegible], should be instilled into the eye only when the parasite has been located in a suitable position for removal. This point is important, because it is essential to have the whole worm in view if the operator is to be sure of removing it. Almost certainly the anæsthetic will arrest the worm in this position. The conjunctiva should be snipped with a pair of very fine scissors parallel with the length of the worm and as near its centre as possible. The worm is then grasped with a pair of fine forceps and removed intact. When no suitable instruments are available, the worm can be removed

LOIASIS

R. D. C. JOHNSTONE
M.D. Lond., M.R.C.P.

LOIASIS is caused by the infection of man with the filaria *Loa loa*, whose other names, all associated with the eye, are African eye-worm, *Dracunculus oculi*, and *Filaria oculi humani.*

Loiasis was first observed and recorded pictorially by Pigafetta in 1598 on his journey along the Congo river. In 1770 a worm was removed from the eye of a negress in Haiti by Mongin. In 1777 loiasis was accurately observed by Guyet in Angola, and in 1805 he wrote the first description of the disease. Manson (1891) first demonstrated microfilariæ in the blood of an infected patient. The original discovery of the intermediary host must be accredited to Manson, but it was not until 1913 that Leiper proved Manson's observations to be correct.

Infection by *Loa loa* is limited to Africa, chiefly along the west coast from Sierra Leone to Benguella but also extending inland as far as equatorial Sudan, which shows a high incidence. Probably the areas which show the heaviest infection are the Cameroons and the borders of the Congo river. The condition was formerly common in the West Indies and America but is now only rarely seen there, and the cases recorded are universally held to have been due to infection in Africa. There is no fly vector in the American continent which carries the disease.

LIFE-CYCLE AND DESCRIPTION OF PARASITE

Man is infected by the bite of the mangrove fly, of the species *Chrysops dimidiata* and *C. silacea*, though there is strong evidence that other flies may at times carry the disease.

The female chrysops, which bites during the day, deposits the larvæ on the victim's skin, through which they burrow in no more than a minute. Apparently the larvæ move into the deeper tissues, where they grow into adult worms. Opinions differ about the rate of growth and the time taken by the worms to mature, but it seems certain that they reach their full size within a few months. It is probably some years before they produce microfilariæ, and during this period they wander about the body, passing freely through the connective tissues; their rate of progress may be as much as $^1/_2$ in. a minute.

After a variable period the female filariæ produce microfilariæ, which enter the blood-stream. Some say that at least three years elapse between infection and the appearance of microfilariæ in the blood. It is generally held that the microfilariæ are strictly diurnal, but this fact is denied by some. Possibly there is some confusion with microfilariæ of *Acanthocheilonema perstans*, but it is certain that the microfilariæ of *L. loa* are far more plentiful during the day than the night. Their periodicity is therefore in sharp contrast to that of the microfilariæ of *Wuchereria bancrofti*, which are definitely nocturnal.

To complete the life-cycle of *L. loa* it is necessary for the infected person to be bitten again by a chrysops, whereupon the microfilariæ pass into the insect's stomach with the blood and later migrate to its thoracic muscles. Here they undergo morphological changes without multiplication, and finally pass to the proboscis, where they await their new host. The cycle in the fly lasts 10–12 days.

The adult filariæ are $^3/_4$ to $2^1/_2$ in. long, the females being somewhat longer than the males. They are white and resemble a thick thread of cotton. The microfilariæ are about 300 μ long and about equal to a red corpuscle in diameter.

CLINICAL PICTURE OF LOIASIS

Both sexes and all races, including young children, are liable to infection, and in heavily infected areas some 20% of the inhabitants are infected.

Many writers say that loiasis is harmless and almost symptomless, causing no disability, but I cannot agree with them. For several years after leaving an endemic area it is common for no symptoms to appear, and cases are recorded in which the first knowledge of infection was five years after return to a temperate climate.

Calabar Swellings.—These are by far the most common symptom. They are so named after the town in Nigeria where the disease is rife. Usually there is a fairly sudden onset of a swelling $1^1/_2$–2 in. in diameter, which lasts as a rule three to five days and is most common on the forearm. The swelling may irritate slightly and show minimal pitting and occasionally redness of the overlying skin. Apart from an ache these swellings cause no great disability, unless they are close to a joint or a nerve. They gradually shrink, but at times they seem to move their position. It is said that even in heavily infected cases only a very few swellings will appear each week. In my opinion their number is almost unlimited at any one time—indeed, several may appear together. After the patient's return to a temperate climate the swellings tend to become less frequent and eventually disappear, though the adult filariæ may persist. The swellings may first appear within four months of the patient's arrival in an endemic area, or they may not develop until many years after infection.

Distribution of Filariæ in the Body.—The filariæ most commonly appear near the eyes, for which they seem to have a predilection, and few patients have not at some time had a worm in this region. It is in this area that their movements are most easily felt, and they can often be seen wriggling under the loose skin of the lids. Commonly they cross the eye, passing easily and rapidly under the conjunctiva. While they are in this region they may cause swelling, conjunctivitis, lacrimation, and pain. The worms have been seen in the eye within nine months of infection. They have been removed from an eye thirteen years after the patient has left an endemic area, and live filariæ have been seen fifteen years after the patient's return to a temperate climate. The worms may be seen under the skin in many parts of the body, such as the back of the hands, the nose, the penis, and elsewhere. Their movements when close to the surface of the skin cause paræsthesiæ, creeping sensations, and itching.

Eosinophilia.—This is an absolutely constant finding, but after a long period in a cold climate the count tends to fall almost to normal. The average count is 15–30%, the highest recorded being in a European with a count of 84%.

Psychological Effects.—Most authors do not even mention this aspect of the disease, and I can find only two references to it. Elliot (1920) writes: "The combination of itching, pain, and irritation caused by the movements of the parasite under the conjunctiva are simply maddening." Clothier (1943) writes: "If a worm is not removed but merely driven into the deeper tissues by cold applications, it frequently returns many times to harass a tired and overworked individual until a partial nervous breakdown is the end-result."

The constant creeping sensation caused by the filaria under the skin of the face for hours or even days on end is indeed distressing, and the relief afforded by removal of the worm cannot be adequately appreciated by an observer. The knowledge that probably many more parasites are present in the body, or the discomfort of removing the worm, can in no way detract from the satisfaction felt at seeing the immediate cause of the trouble safely removed.

Less Common Manifestations.—Various skin eruptions, including a generalised urticaria, have been recorded. Nausea, headaches, œdema of the glottis, transient

THE PAINFUL NODULAR BREAST

A PLEA FOR THE TERM FIBRO-ADENOSIS

H. J. B. Atkins
D.M., M.Ch. Oxfd, F.R.C.S.
DIRECTOR OF THE SURGICAL DEPARTMENT, GUY'S HOSPITAL

A SUITABLE name is required for the painful nodular breast not due to bacterial inflammation, neoplasm, or fat-necrosis. There is no lack of choice of names which have been applied to this condition—e.g., chronic mastitis, cystic mastitis, interstitial mastitis, cystadenoma papilliferum, involution cysts, cystic disease of the breast, Schimmelbusch's disease, mazoplasia, and chronic cystipherous epithelial hyperplasia. It is a reflection on the unsuitability of these names that the one most commonly used is chronic mastitis, a name which is descriptively as unsatisfactory as any, but has been sanctioned by long usage. Before adding another name to this list, therefore, it is necessary to make out a strong case for its exclusive adoption, and I wish to argue the claims of the term "fibro-adenosis" to describe the condition defined above.

What, in medicine, are the requisites of a name? It should tell us as much as possible about the condition in the shortest possible way. It should be easy to remember and pronounce, and suggest familiar associations. Further, it must not commit us to any as yet unproved hypothesis. In looking for a name, therefore, we must first review what is known about the painful nodular breast so as to include in our name as much of the ætiology, structure, and symptoms as possible.

ÆTIOLOGY AND STRUCTURE

Ætiology.—We know nothing of the ætiology of the painful nodular breast except that it is probably the consequence of a hormonal effect; and, since our knowledge is so meagre, all that we need ensure is that the name selected does not commit us to any preconceived theory.

Macroscopical Appearance.—When we examine the naked-eye and microscopical structure of the painful nodular breast we are on sure ground. To the naked eye a section from the affected part of the breast suggests a mass of fibrous tissue ramifying in the breast without definite boundaries, in which there may or may not be cysts containing clear, grumous, or grey fluid. In over a hundred biopsies taken from breasts affected by this condition I have found cysts, sufficiently large to be visible to the naked eye, in a very small proportion of cases. This is a significant finding when we are seeking a name for the condition, for it implies that cyst formation is a secondary, not an essential, change; and this complication should not be indicated in the name as a fundamental part of the picture. The prefix "cystic" may be added, should it be necessary to emphasise this quality, just as we add "cystic" to "fibro-adenoma" when the cystic changes predominate.

Histology.—When we examine the stained section under the microscope, the fibrous quality of the specimen is confirmed. There is intense fibroblastic activity both in the periacinous and subepithelial connective tissues, particularly in the former; but, in addition, epithelial changes are observed. These have been described so accurately and so often elsewhere that it will not be necessary to go into them in detail. Suffice to say here that there is a hyperplasia of the epithelial tissue; the number of acini is increased, and the epithelium of the individual acinus is hyperactive. Dilated ductules become lined with cells many layers thick, and the superficial cells are thrown off as debris into the lumen. Here and there papillomata may project and tend eventually to fill the lumen of the ducts or ductules with a delicate lace-work of epithelium supported by a fibrous stroma. This hyperplasia of the glandular epithelium may properly be called an adenosis. This term has been used by Dawson (1934) to describe only part of the process—i.e., the multiplication of the glandular elements. Nevertheless, it may justifiably be extended to cover the epithelial changes within those elements, a task which it already bears in the connotation of the term adenoma.

Finally, the specimen contains fat.

Were we to consider only the structural picture of the painful nodular breast, the term fibro-adenosis must have an almost irresistible appeal. It describes precisely what is found, it makes no claim which cannot be substantiated, and it emphasises the two primary changes of the condition. But there are other considerations.

SYMPTOMS

The symptoms of this condition are lumpiness and pain. The lumpiness is due to fibrosis or cyst formation; and, as the cysts cause the lumpiness in a minority of cases and then only as a complication of a pre-existing lumpiness due to the fibrosis, the lumpy quality is sufficiently indicated in the term fibro-adenosis, which, as we have seen, may be qualified if necessary by the epithet "cystic."

How about the pain? For some time I considered the possibility of the term "fibrous mastalgia" to describe the condition, but I concluded that this term was too indefinite, made no reference to the epithelial changes which are fundamental, and suggested no link with the allied condition of fibro-adenoma. On closer examination, moreover, the term fibro-adenosis suggests a painful condition. The suffix "osis" implies a diffuse rather than a localised process such as is connoted in the suffix "oma." Vertue (1946) discusses the etymological significance of the suffix "osis" and points out that it denotes action or condition. By his definition "fibro-adenosis" should mean "a condition of fibrotic glandularity," and that is just what we wish it to mean. All diffuse fibroblastic activity in structures supplied with nociceptive nerves is painful, as for instance in "fibrositis," fasciitis, fibrillation of synovia in osteoarthritis, and Riedel's thyroiditis. Further, this "fibroblastic" pain has a tendency to vary with states of the weather, a tendency which is shared by the painful nodular breast. I therefore considered that the term fibro-adenosis, while giving a precise picture of the structural form of the condition, at the same time sufficiently indicated the clinical picture.

RELATION TO FIBRO-ADENOMA

The term further suggests an association with fibro-adenoma, and it will be necessary to justify this association before it can be perfectly acceptable. Let us turn first to the histological and clinical aspects. Histologically, with ordinary methods of staining, the only difference between the painful nodular breast and the painless fibro-adenoma, conditions which may in fact coexist in adjacent parts of the same breast, is that the painful nodular breast contains fat, whereas the fibro-adenoma does not. Fibro-adenoma is, moreover, usually supplied with a well-defined fibrous capsule. Otherwise the fibrous and epithelial changes are precisely similar, as is shown by the accompanying figure, the left-hand column being photomicrographs of sections of the painful nodular breast and the right-hand column of fibro-adenoma.

with a cutting needle, but the operation takes longer and is more difficult.

When a worm has been located under the skin and can easily be seen, it should be removed by passing a fine stitch under it and tying it securely. This stitch should be inserted without local anæsthetic, because the parasite tends to become obscured by the injected drug. Once it has been firmly secured it may be removed without hurry through a small incision after injection of local anæsthetic.

CASE-RECORD

I reached West Africa at the end of June, 1943, and, after two weeks in Sierra Leone, proceeded to Southern Nigeria, where I remained for the next year working in a casualty clearing station. During this period we were always stationed in the bush, conditions being usually somewhat primitive, since we were under canvas much of the time. The surrounding country was thick tropical forest, and I often made trips into this during my spare time to collect butterflies. There was therefore ample opportunity for being bitten by flies of all sorts. Except for M.T. malaria and bacillary dysentery, my health was good. I was moved to Accra, Gold Coast, in June, 1944, where the conditions by comparison were excellent and civilised.

In July-August, 1944, I first noted the gradual onset of a swelling above the right wrist. This was pronounced to be a sprain, but the swelling gradually spread to involve the whole of the right hand, and writing for more than a few minutes caused cramp. Although daily massage seemed to help considerably, the condition persisted to such an extent that playing any games which involved holding a handle was impossible.

At this stage, and lasting about ten days, a severe neuralgia in the distribution of the right median nerve came on regularly every night, and at no time during this period did I manage to sleep more than twenty minutes at a time. Getting out of bed and moving the hand removed the pain and tingling within a minute or so, but tying the hand up with a sling to the mosquito netting did not help. Later I found that the somewhat excessive intake of alcohol during the evening helped considerably in giving me a restful night. At this time the maximal swelling was in the centre of the palm.

Gradually these unpleasant symptoms passed off, and the nights which I had come to dread became more peaceful. The swelling of the wrist and hand persisted for at least 6–8 weeks. Slight pitting œdema was always present, but apart from the short period mentioned above there was little interference with my work or normal activities.

Within a few weeks of the appearance of the first swelling a regular crop of swellings kept coming and going. In one week in October, 1944, I had 16 swellings, 3 coming in one day. At times they were irritating and the overlying skin red; at other times they appeared to be situated more deeply, causing an ache which usually felt like a bruise and lasted twenty-four hours. By far the greatest number developed on the forearms, but few parts of my body have so far escaped. Throughout the disease the eosinophilia has ranged between 36% and 12%. Repeated search for microfilariæ has always been negative.

I left West Africa in December, 1944, the journey to England taking four weeks. The weather was extremely cold, and with the fall in temperature there was a noticeable decrease in the number of swellings. In fact, by the time that I reached this country I was getting about one every third day at the most.

The night before we docked I noted discomfort in the right eye; and, though I suspected a worm as the cause, I could see nothing abnormal, and the feeling passed off. Next evening there was a repetition of this symptom, followed shortly by a creeping sensation on the globe. There was no difficulty in seeing the filaria under the conjunctiva, and it was removed intact with a needle after cocainising the eye. The procedure took some twenty minutes and was unpleasant but not really painful. Any unpleasantness was well worth the sense of relief which I felt on knowing that the worm had been removed. A mild conjunctivitis persisted for several days.

During the following months Calabar swellings developed at an average of about two a week. A second filaria made its first appearance about the last week in June, 1945, near the left eye, and for the next two and a half days it wandered round the eyelids, sometimes passing across the bridge of the nose but always returning to the same eye. It gave the impression that it was anxious to find the conjunctiva but could not do so. During this time it caused no true swelling, but often I could see it clearly under the loose skin of the lids, and throughout the day and the night I was constantly aware of its presence, as it seldom remained in any one position for more than a few moments.

After consultation with an ophthalmologist it was decided that, should the worm appear in the upper lid again, an attempt should be made to remove it. This was most ably carried out in the following manner. A stitch was passed under the filaria when it next appeared, and the suture was tied firmly. Local anæsthetic was then infiltrated and the whole worm removed intact, the small wound being closed with a suture. There was a moderate degree of swelling of the orbital tissues which lasted several days. I cannot recommend this method of removal as simple or completely painless, and the possibility of a portion of the worm being left behind and thus causing suppuration near the inner canthus must be borne in mind.

A third worm appeared near the right eye in August, 1945. Like its predecessor, it spent some days wandering round, but it differed in the fact that at one time it coiled itself in the outer aspect of the upper lid and formed a small Calabar swelling. Next morning it continued its movements, again crossing the nose but returning to the eye a few hours later. Several people have advocated the removal of the worm while it is crossing the nose, but I took most careful note of both these worms, and at no time was it really possible to discern them under the skin in that position.

At this time I had to go to London and was therefore unable to remain near medical assistance, should the worm appear under the conjunctiva. Later in the day I was fortunate enough to be in a London hospital, when I suddenly experienced the most acute pain deep in the right eye. This pain extended up over the frontal region to the top of the head. It was grossly aggravated by even the slightest movement of the eyes, and it was the worst pain that I have ever experienced. No worm had been visible or felt to be moving for about half an hour before the onset of this pain. These symptoms persisted for one and a half hours and then equally abruptly ceased, leaving nothing more than an ache, which was worst when the eye was turned. Fifteen minutes later the filaria could be felt crawling over the inner aspect of the *conjunctiva, having apparently emerged* from the inner canthus. It was rapidly and most efficiently removed by the sister in charge of the ophthalmic department.

The fourth worm was removed from my right eye after wandering round that region for over two weeks. Like the others, it seldom seemed content to stay quiet in one place, and throughout this period it was an almost constant source of annoyance and discomfort. Owing to lack of suitable instruments its removal was possibly somewhat slow, necessitating three lamellæ of cocaine. This dosage appeared to paralyse it, and there was little urgency in removing it, as it became almost motionless under the conjunctiva.

As I write this, my right hand and wrist are slightly swollen, having been like this for over a month, but there are no localised Calabar swellings.

The course taken by the Calabar swellings throughout the last nine months is of interest, as during the hot summer months they were most frequent but never exceeded three in a week. During the cold weather they have been distinctly uncommon. Even their character has altered, in that they are more transient, and indeed, if I did not know that I had the disease, they might pass unnoticed.

SUMMARY

Loiasis is a chronic condition, not amenable to any specific treatment, and may well be encountered in this country for years to come.

Removal of the worms should always be attempted when they are crossing the eye.

The mental distress which the filariæ cause in their wanderings should not be lightly disregarded.

Treatment with toxic drugs is not justifiable in any circumstances, since the possibility of permanent damage or disability resulting from the disease is almost negligible.

My own case-record is given in full, but it covers only a brief period of a long disease. It does, however, show most of the important points and is remarkable in that already four filariæ have been removed.

THE PAINFUL NODULAR BREAST

A PLEA FOR THE TERM FIBRO-ADENOSIS

H. J. B. ATKINS
D.M., M.Ch. Oxfd, F.R.C.S.
DIRECTOR OF THE SURGICAL DEPARTMENT, GUY'S HOSPITAL

A SUITABLE name is required for the painful nodular breast not due to bacterial inflammation, neoplasm, or fat-necrosis. There is no lack of choice of names which have been applied to this condition—e.g., chronic mastitis, cystic mastitis, interstitial mastitis, cystadenoma papilliferum, involution cysts, cystic disease of the breast, Schimmelbusch's disease, mazoplasia, and chronic cystipherous epithelial hyperplasia. It is a reflection on the unsuitability of these names that the one most commonly used is chronic mastitis, a name which is descriptively as unsatisfactory as any, but has been sanctioned by long usage. Before adding another name to this list, therefore, it is necessary to make out a strong case for its exclusive adoption, and I wish to argue the claims of the term "fibro-adenosis" to describe the condition defined above.

What, in medicine, are the requisites of a name? It should tell us as much as possible about the condition in the shortest possible way. It should be easy to remember and pronounce, and suggest familiar associations. Further, it must not commit us to any as yet unproved hypothesis. In looking for a name, therefore, we must first review what is known about the painful nodular breast so as to include in our name as much of the ætiology, structure, and symptoms as possible.

ÆTIOLOGY AND STRUCTURE

Ætiology.—We know nothing of the ætiology of the painful nodular breast except that it is probably the consequence of a hormonal effect; and, since our knowledge is so meagre, all that we need ensure is that the name selected does not commit us to any preconceived theory.

Macroscopical Appearance.—When we examine the naked-eye and microscopical structure of the painful nodular breast we are on sure ground. To the naked eye a section from the affected part of the breast suggests a mass of fibrous tissue ramifying in the breast without definite boundaries, in which there may or may not be cysts containing clear, grumous, or grey fluid. In over a hundred biopsies taken from breasts affected by this condition I have found cysts, sufficiently large to be visible to the naked eye, in a very small proportion of cases. This is a significant finding when we are seeking a name for the condition, for it implies that cyst formation is a secondary, not an essential, change; and this complication should not be indicated in the name as a fundamental part of the picture. The prefix "cystic" may be added, should it be necessary to emphasise this quality, just as we add "cystic" to "fibro-adenoma" when the cystic changes predominate.

Histology.—When we examine the stained section under the microscope, the fibrous quality of the specimen is confirmed. There is intense fibroblastic activity both in the periacinous and subepithelial connective tissues, particularly in the former; but, in addition, epithelial changes are observed. These have been described so accurately and so often elsewhere that it will not be necessary to go into them in detail. Suffice to say here that there is a hyperplasia of the epithelial tissue; the number of acini is increased, and the epithelium of the individual acinus is hyperactive. Dilated ductules become lined with cells many layers thick, and the superficial cells are thrown off as debris into the lumen. Here and there papillomata may project and tend eventually to fill the lumen of the ducts or ductules with a delicate lace-work of epithelium supported by a fibrous stroma. This hyperplasia of the glandular epithelium may properly be called an adenosis. This term has been used by Dawson (1934) to describe only part of the process—i.e., the multiplication of the glandular elements. Nevertheless, it may justifiably be extended to cover the epithelial changes within those elements, a task which it already bears in the connotation of the term adenoma.

Finally, the specimen contains fat.

Were we to consider only the structural picture of the painful nodular breast, the term fibro-adenosis must have an almost irresistible appeal. It describes precisely what is found, it makes no claim which cannot be substantiated, and it emphasises the two primary changes of the condition. But there are other considerations.

SYMPTOMS

The symptoms of this condition are lumpiness and pain. The lumpiness is due to fibrosis or cyst formation; and, as the cysts cause the lumpiness in a minority of cases and then only as a complication of a pre-existing lumpiness due to the fibrosis, the lumpy quality is sufficiently indicated in the term fibro-adenosis, which, as we have seen, may be qualified if necessary by the epithet "cystic."

How about the pain? For some time I considered the possibility of the term "fibrous mastalgia" to describe the condition, but I concluded that this term was too indefinite, made no reference to the epithelial changes which are fundamental, and suggested no link with the allied condition of fibro-adenoma. On closer examination, moreover, the term fibro-adenosis suggests a painful condition. The suffix "osis" implies a diffuse rather than a localised process such as is connoted in the suffix "oma." Vertue (1946) discusses the etymological significance of the suffix "osis" and points out that it denotes action or condition. By his definition "fibro-adenosis" should mean "a condition of fibrotic glandularity," and that is just what we wish it to mean. All diffuse fibroblastic activity in structures supplied with nociceptive nerves is painful, as for instance in "fibrositis," fasciitis, fibrillation of synovia in osteoarthritis, and Riedel's thyroiditis. Further, this "fibroblastic" pain has a tendency to vary with states of the weather, a tendency which is shared by the painful nodular breast. I therefore considered that the term fibro-adenosis, while giving a precise picture of the structural form of the condition, at the same time sufficiently indicated the clinical picture.

RELATION TO FIBRO-ADENOMA

The term further suggests an association with fibro-adenoma, and it will be necessary to justify this association before it can be perfectly acceptable. Let us turn first to the histological and clinical aspects. Histologically, with ordinary methods of staining, the only difference between the painful nodular breast and the painless fibro-adenoma, conditions which may in fact coexist in adjacent parts of the same breast, is that the painful nodular breast contains fat, whereas the fibro-adenoma does not. Fibro-adenoma is, moreover, usually supplied with a well-defined fibrous capsule. Otherwise the fibrous and epithelial changes are precisely similar, as is shown by the accompanying figure, the left-hand column being photomicrographs of sections of the painful nodular breast and the right-hand column of fibro-adenoma.

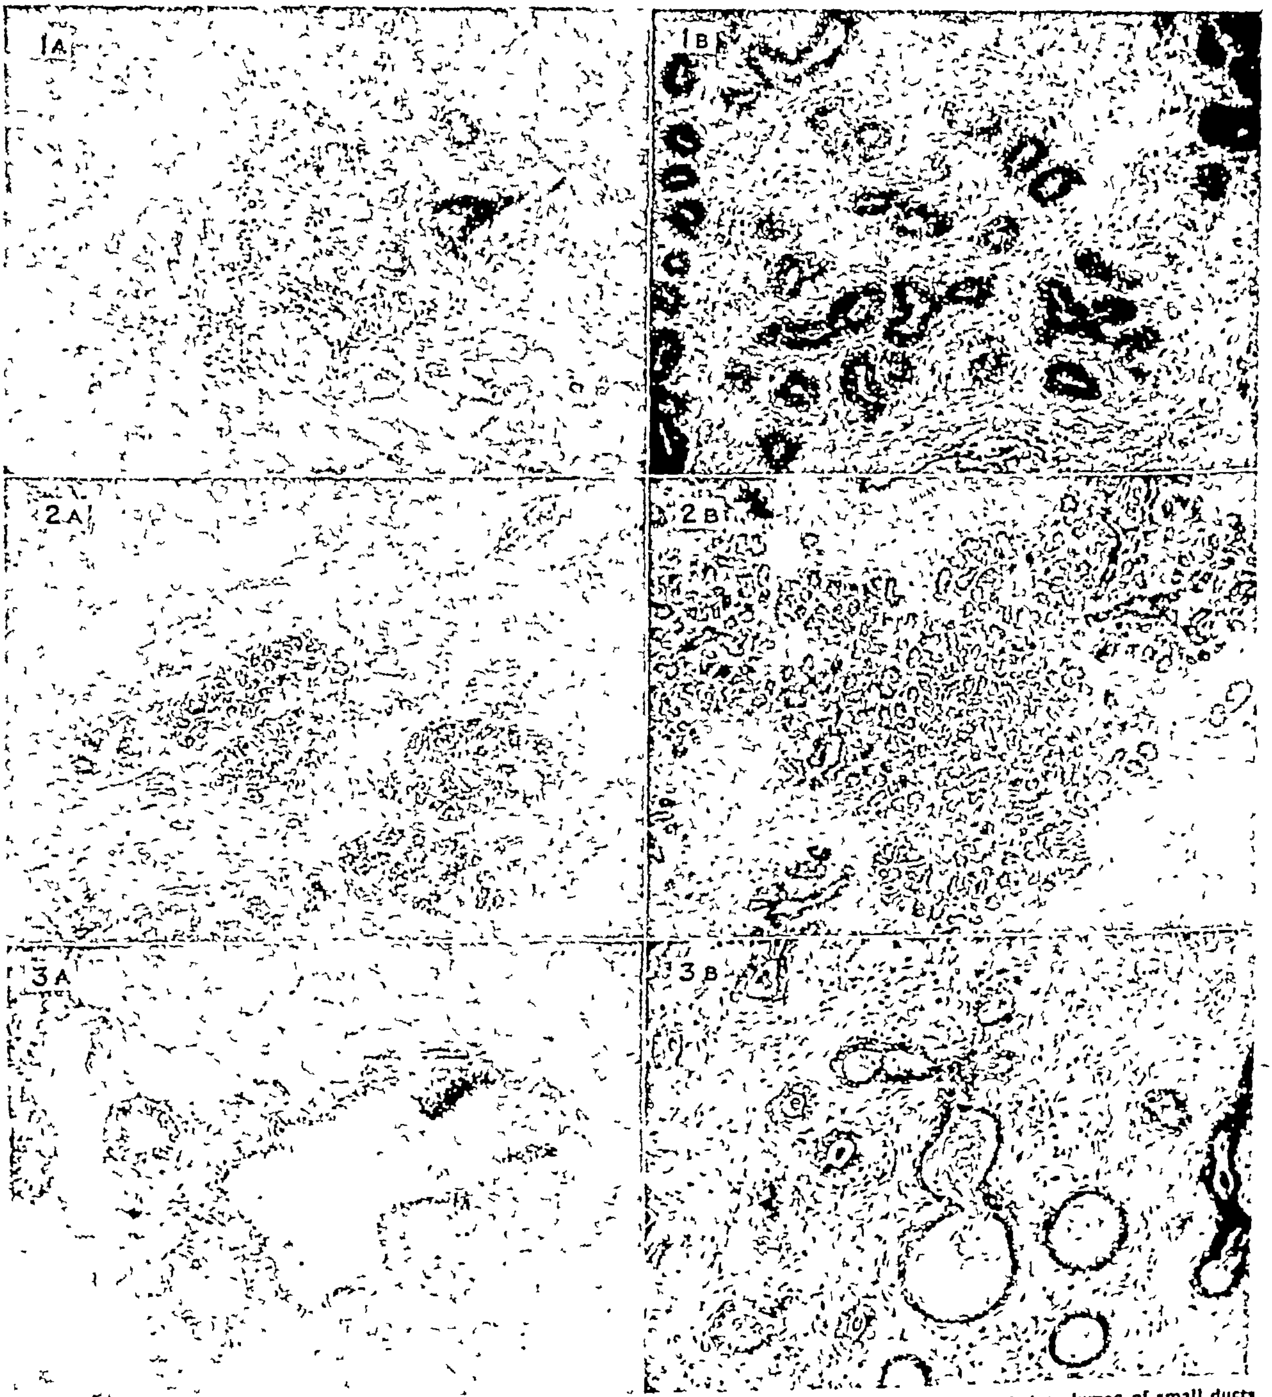
It is true that the epithelial changes are inclined to be more advanced more commonly in what we may agree temporarily to call fibro-adenosis, and this is a point to which I shall return later. The presence of fat in the fibro-adenosis indicates how diffuse it is. The process infiltrates and incorporates all the structures in the organ, including the fat and the nerves; hence its painful nature. Fibro-adenoma, on the other-hand, is localised. It probably arises in one acinus and, generating a formidable fibrous-tissue barrier, is everywhere exclusive of the remaining breast tissue. It expands by pushing the surrounding structures out of the way rather than by incorporation; thus it comes about that it contains no fat, excludes all nerves, and is painless. It is submitted that these differences, comparable to those existing between endometriosis and endometrioma, are nicely comprehended in the terms fibro-adenosis and fibro-adenoma.

In discussing the ætiology of fibro-adenosis I had to admit that our knowledge was scanty and inexact; the same must be said of our knowledge of the ætiology of fibro-adenoma. If, however, we are ignorant of this ætiology we have grounds for suspecting that the unknown cause is the same or similar in the two conditions. If it



Photomicrographs of fibro-adenosis (A) and fibro-adenoma (B): 1, early epitheliosis, with desquamation of cells into lumen of small ducts (note fat-cells along the right-hand margin and bottom edge of A, and absence of fat in B) (× 130); 2, alveolar arrangement common to all hyperplastic conditions of the breast (note fat-cells above the alveoli in A, and absence of fat in B) (× 78); 3, early cystic dilatation of ducts, with hyperplasia of lining epithelium and desquamation (note ducts are embedded in fat in A, and there is no fat in B) (× 130).

The time seems to have come when the physician, confronted by the patient convalescing from an acute rheumatic attack, must seriously consider instituting sulphonamide prophylaxis. The great objection to such a course in general practice is the need for frequent blood-counts to forestall toxic reactions. In a scattered rural community, such as that from which the patients under review are drawn, this difficulty is almost unsurmountable because of the distance from a pathological laboratory. Also, it is not always possible to keep the necessary close supervision over patients engaged in their ordinary occupations. It was hoped that penicillin might offer a way out of these difficulties and still provide a safe and effective alternative to the sulphonamides in the prophylaxis of acute rheumatism.

The findings in this small group of patients, who had acute rheumatism preceded by throat infections and were treated with penicillin by mouth, show a considerable reduction in the incidence of both pharyngitis and rheumatism in comparison with an untreated group of similar types of patients over twelve months. It is hoped that these findings will lead physicians with laboratory facilities to investigate this form of prophylaxis.

SUMMARY

A group of ten rheumatic patients were treated prophylactically with penicillin by mouth for a year, and the clinical findings were compared with those in an untreated group of similar patients.

Rheumatic manifestations were five times more frequent, and throat infections six times more frequent, in the control group than in the treated group.

Hypometabolism

A clinical study of 308 *consecutive cases.* ESBEN KIRK, chief physician, Holstebro District Hospital, Denmark; SVEN ANCHER KVORNING, assistant, pharmacological department, University of Copenhagen. Copenhagen: Munksgaard. London: W. Heinemann. Pp. 83. 7*s.* 6*d.*

HOLSTEBRO is a country district in north-west Jutland, and until recently there was no organised medical service there. During the years 1940–42, 308 patients with basal metabolic rates below 88% of the normal were admitted to the district hospital, and this small monograph describes the analysis of these data. No indication is given of the number of patients with normal metabolic rates who were admitted in the same periods, so the authors are really only concerned with the reasons for the low B.M.R.s, and the symptoms to which they may have given rise. Only 18 of the 308 patients had genuine myxœdema, but 11 more had had treatment for exophthalmic goitre; 41 are attributed to undernutrition due to gastro-intestinal disease, anorexia nervosa, and vegetarianism, and the reason for the low B.M.R. remained undiagnosed in 108. Over 30 signs and symptoms were investigated in each of these patients, and the greater part of the monograph is taken up with tables showing the frequency with which such things as chilliness, decreased sweating, and impaired memory appeared in the patients in each of the diagnostic groups. This part of the book is almost unreadable and can be recommended only for reference. The authors give their findings for these symptoms in a control group, and conclude that the hypometabolism detected in many of these patients has no pathological significance. This really amounts to saying either that the normal rating is too high or that normal people may have B.M.R.s above and below the accepted range of normality. The monograph will have a limited appeal but it may be found useful by those concerned with the various manifestations of undernutrition seen in many parts of Europe today.

Practical Methods for the Microbiological Assay of the Vitamin B Complex and Essential Amino-acids

E. C. BARTON-WRIGHT, D.SC., F.R.I.C. London: Ashe Laboratories. Pp. 58. 7*s.* 6*d.*

MANY bacteria are nutritionally exacting towards a variety of vitamins and amino-acids, and this fact has been made the basis of methods of estimation of these growth substances.

In principle, the method consists in taking a medium which is nutritionally satisfactory in all respects with the exception of the one substance which is to be assayed. The amount of growth of an organism which is nutritionally exacting towards that substance will then depend upon the amount of that substance which is added to the medium, and a "standard" curve can be constructed to represent the growth which occurs in relation to the amount of assay substance present. The amount of this substance in an unknown solution can then be estimated by determining the amount of growth which it will promote at various levels of concentration of the unknown. The method thus involves: (1) preparation of a satisfactorily nutrient medium in which growth will be conditioned *solely* by the amount of assay substance added; (2) preparation of a standard inoculum; (3) removal of assay substance from medium and inoculum to give a satisfactory blank in the absence of added factor; (4) construction of an accurate and reproducible response curve; (5) quantitative recovery of assay substance from materials to be assayed; and (6) an accurate method of observation of the growth of the organism or of some consequence of growth such as fermentation acid.

Dr. Barton-Wright gives an elementary outline of the media, organisms, and practical methods involved in such studies for the assay of various vitamins and certain amino-acids; but his account is misleading about this difficult technique, which is still under investigation. He claims that "microbiological assay with the lactic acid bacteria is straightforward and presents no great difficulties," which is about on a par with saying "life is simple." The technique of this type of assay has only been developed within the last few years, and the little experience so far obtained serves mainly to emphasise how complicated interpretation of results may be. Results can be turned out so rapidly and easily that the method encourages a deceptive sense of accuracy in the operator; consequently a book of this kind should carry full warning of the likely errors.

The analyst undertaking assays of amino-acids, for example, must consider: how many estimations are necessary for each point on the curve in order to get a statistically accurate result; what degree of scatter can be expected and is permissible; how quantitative are the extraction procedures used and how has this been determined; what is the effect of the presence of peptides on amino-acid analysis; what percentage of assays with neurospora mutants show a reversion to wild type; what is the effect of salt content or buffering capacity of assay material; and how is the size of the inoculum controlled and standardised? This book does not answer these queries and does not hint that such questions arise.

Die Scheuermannsche Krankheit

J. E. W. BROCHER, dozent, University of Geneva. Basle: Benno Schwabe. Pp. 91. Sw. fr. 11.

THIS monograph is more than a description of adolescent kyphosis. As a disciple of Schmorl, Dr. Brocher has tried to correlate the radiological signs of disk pathology with clinical symptoms, and has produced an interesting study of Scheuermann's disease. He rightly stresses the frequency with which this apparently benign condition gives rise to chronic pain and disability in later life, as the result of arthritic changes in the mobile segments of the spine above and below the immobile and painless kyphos. The less common but more disabling lumbar form of the disease is given the prominence it deserves. On ætiology he has little new to offer us, but those inclined to attribute all low-back pain to posterior prolapse of the intervertebral disk might do worse than study this carefully written monograph.

1947 marks the 150th anniversary of the foundation of

HOWARDS OF ILFORD

who hope that this year will confirm and strengthen the ties between their many customers and themselves. They hope, furthermore, to overcome some of the difficulties which beset them in the past year, enabling them to offer greater supplies of their products in 1947.

Vitamin Therapy—its uses and limitations

CONVALESCENCE

The period of debility following acute illness—as, for example, influenza and pneumonia—calls for special care, because of the tendency to relapse and the lowered resistance to other infections. Modern work indicates that this state is due in no small measure to sub-normal nutrition from the restricted food intake during illness and also partly to the increased utilisation of certain food factors during the infection.

COMPLEVITE

a *single* supplement for *multiple* deficiencies

The recommended daily dose provides.

vitamin A	4,000 i.u.	calcium	160 mg.
vitamin D	300 i.u.	iron	68 mg
vitamin B_1	0.6 mg.	iodine manganese copper	not less than 10 p.p.m. each
vitamin C	20 mg.

THE LANCET

LONDON: SATURDAY, FEB. 15, 1947

Crisis and Recovery

THE Proprietors of THE LANCET regret that restrictions in the use of electric power will prevent normal production and distribution of the journal during the next two or three weeks. Everything possible will be done to minimise inconvenience thus caused.

Our thoughts inevitably go back to the General Strike of 1926, when our weekly issue was reduced to a single sheet; and it is natural to compare the two crises. Today's, though less acute, is more serious, because the country has less reserve of strength. But it has a redeeming feature: instead of two hostile groups facing one another, we now see a whole nation facing mankind's proper and eternal enemy—the scarcity of means to live. If opinions differ widely, as they do, on how best to keep the wolf from the door, we are at least united in wanting to drive him far away. By any method this will take time. When HITLER boasted that if Germany was defeated she would bring us down with her, he came all too near the truth: at best there must be a long period during which even our present standard of living will remain in danger. Our resources have been exhausted by war; and once again, for the third time in a generation, some of our friends doubt our capacity to make the necessary response. But for the third time it will be made. As at the end of the war in Europe, we recall Mr. CHURCHILL's saying that the mettle of a nation, as of a man, is proved by what it can do when it is tired. What we have to do now, though irritated and dispirited and perhaps underfed, is to work for material security and prosperity. But even this is not enough: we have also to work for social justice. To pursue simultaneously recovery and reform is difficult, yet neither the quantitative nor the qualitative aim will succeed unless we attempt both We cannot truly serve ourselves unless we serve what we believe to be civilisation; for recovery from sickness depends largely on hope of better things to come

Treatment of Toxic Goitre

SINCE we are ignorant of the primary cause of toxic goitre, treatment aims at the reduction of thyroid hypersecretion. Until 1943 this was achieved satisfactorily only by subtotal thyroidectomy. But since then favourable results have been obtained by purely medical means. Antithyroid drugs, notably thiouracil and its methyl derivative, have proved capable of reducing thyroid function with much the same certainty as the extirpation of thyroid tissue.

Both methods, surgical and medical, have their advantages and drawbacks, and their relative merits cannot be finally assessed on the basis of a mere three years' experience with thiouracil. On another page Professor HIMSWORTH and his colleagues make an interim comparison of about 90 thiouracil-treated patients with an equal number treated surgically in a previous period. From the patients' point of view there is no doubt that most prefer to get well by taking tablets rather than by undergoing a major operation. Moreover surgical treatment means admission to hospital or nursing-home, whereas this is often unnecessary with drug treatment, provided close supervision can be arranged. As to the safety of the two methods, HIMSWORTH found the mortality-rates about the same—2%—but the rates with both treatments are now probably lower than this. The 2% mortality for thyroidectomy done by the expert is a figure from the prethiouracil era; with preoperative detoxication by thiouracil, and perhaps also the avoidance of long domiciliary treatment with iodine, the mortality should be still further reduced. Agranulocytosis accounts for all the thiouracil deaths, and these should become very rare with early recognition and treatment with penicillin, which controls infection till the leucopoietic system has recovered. In their surveys of several thousand cases of thyrotoxicosis treated medically VAN WINKLE and others[1] and MOORE[2] found that the mortality from agranulocytosis was less than 0·5%, with a total incidence of 2·5%. They could find no relationship between the daily dose of the drug and the incidence of agranulocytosis, but the doses given in their cases were on the whole higher than we now know to be necessary. The smallest effective dose is the one of choice. Apart from fatalities, there are some complications in both treatments. With thyroidectomy there may be myxœdema, tetany (rare but distressing), injury to the recurrent laryngeal nerves, and other complications inseparable from any major operation. With thiouracil there are mild or moderate toxic reactions which may make it advisable or necessary to abandon the drug.

Once thyroidectomy is successfully accomplished little is required in the way of aftercare, though account must be taken of recurrences in later years even with a nine-tenths removal of the goitre. With antithyroid drugs treatment cannot be discontinued as soon as symptoms are under control—it must be continued for a long time, perhaps for years, until remission occurs. This remission may be long or short, lasting some months or up to two years, but we still cannot claim that a permanent remission can be obtained. It is perhaps a matter of controlling thyroid secretion until the abnormal pituitary stimulus, or some other disturbance a stage beyond that, has died away, or possibly until the thyroid itself has become relatively unresponsive to higher stimuli It is clear that this is a lengthy process, and too long for the endurance of some patients.

It is too early to say that drugs will supersede thyroidectomy or even that they are a satisfactory alternative. The drugs now being used in this country—thiouracil and its methyl derivative—are reasonably safe when given with proper precautions, and they are almost certain to be improved on in time. The biochemistry of all antithyroid drugs is in an early stage, but we may expect before long that they will be prescribed with as little fear of toxic reactions as are the sulphonamides.

VARICOSE VEINS
the modern treatment

There is strong evidence that 'Ethamolin', exerts a *lasting* beneficial effect in the sclerosing treatment of varicose veins. Treatment is effected with a minimum of discomfort to the patient, and the total amount injected is normally less than 6 cc. 'Ethamolin,' an aqueous solution of 5 per cent monoethanolamine oleate with 2 per cent. benzyl alcohol, produces a firm adherent thrombus. There is no fear of sloughing in the event of accidental leakage from the vein. Being powerfully bactericidal, 'Ethamolin' reduces the risk of infection to a minimum.

With the growing recognition of 'Ethamolin' as a safe and efficient sclerosing agent, the need for operative treatment of varicose veins becomes increasingly rare.

2 cc. ampoules, boxes of 6 and 100.
Bottles of 15 cc. and 30 cc.

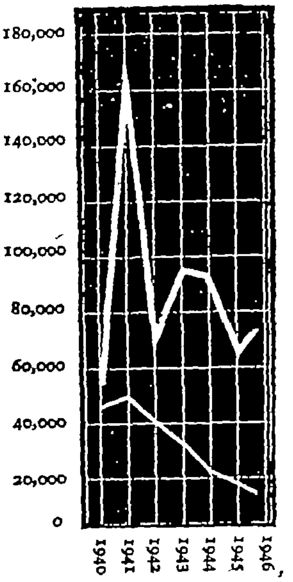
DIPHTHERIA—WHOOPING COUGH
ONE immunological course

The success of the campaign for diphtheria immunisation focuses attention upon the gravity of the figures relating to whooping cough.

For this reason, and for the efficient convenience of doctor, parent and child, Glaxo Laboratories have introduced a new preparation in which the antigens of diphtheria and whooping cough are combined. Named "Diphtheria Prophylactic A.P.T. *plus* Pertussis Vaccine (Alum Precipitated)", this preparation enables *simultaneous* prophylaxis against both diseases to be condensed into a course of three injections (0.5 cc., 0.5 cc., and 1.0 cc.) at monthly intervals. Each cc. contains, in equal proportions, the customary Diphtheria A.P.T. (at least Lf 25) and 20,000 million H. pertussis alum-precipitated.



Left *Thick line* Whooping cough cases notified. *Thin line* Diphtheria cases notified.

Vital statistics embodied in this graph (England and Wales) were supplied by the Minister of Health in the House of Commons on 16th October 1946 (Hansard 1946, 197, 427, 227).

Prefrontal Leucotomy

When Moniz published his monograph on prefrontal leucotomy ten years ago we pointed out that it is not timidity or conservatism that holds up advance in the treatment of mental illness.[1] Since then, more than a thousand patients in Great Britain, and probably a similar number in the United States, have had this *drastic* operation done on them. From statistics collected here, which are reviewed on another page, the Board of Control conclude that "remarkable improvement in behaviour follows in a large percentage of cases who have had severe symptoms with poor prognosis and have failed to respond to other methods of treatment." This resembles the conclusion reached by those who have reported similar mass figures in the U.S.A.—notably Ziegler[2] and Freeman and Watts.[3] A recent acid comment on these statistics is not, however, without pertinence for the Board of Control's figures:

> "Unfortunately, aside from their value as vital statistics, it is impossible to assess the validity of these findings. *At no point have there been other than* superficial attempts made to standardize the criteria for the pre-operative and post-operative clinical status of the patients. Not a single patient has been adequately studied. For a *moral and social responsibility* to do this, there has been substituted a phenomenal array of case statistics. Unfortunately the pyramiding of unknowns is scarcely a pathway to knowledge."[4]

Halstead, Carmichael, and Bucy, in this uncompromising passage, are taking for granted more rigorous standards of "adequate study" than *clinicians commonly satisfy or administrators expect*; and though, as the board point out, the returns they summarise were mostly compiled during the distractions and shortages of the war, and represent remarkable and praiseworthy effort on the part of those who supplied them, this makes it all the more necessary to interpret the results cautiously. It would be churlish to quarrel with the board's interesting report for not answering some crucial questions, which mass returns from forty different hospitals could not possibly elucidate—the postoperative changes in personality, for example. *It is essential* however that the inevitable crudity and uncertainty of such figures as these should be recognised, and that they should be classed and valued as vital statistics rather than as trustworthy data which permit the therapeutic range, the indications, and the risks of the operation to be judged It is easy to infer too much from lumping together disparate reports, just as it is easy, at the other extreme, to generalise falsely from the intensive study of a single instance or a small series. The former extravagance is perhaps the commoner when a *method of treatment has been in* use for some years, and it may be seen in a recent pronouncement on leucotomy: "if further reports confirm the high percentage of desirable results, it should become a routine procedure in mental hospitals."[5] The report of the Board of Control is free from such intemperance, and its last word is a plea for caution: "we are of the opinion that the operation should be carried out only after careful consideration of each individual case by experienced psychiatrists"

Another moral, and perhaps a less obvious one, to be *drawn from this report is that when a severe new* method of treatment is to be tried in psychiatry, or anywhere else in medicine, those employing it are under an obligation to carry out their share of the therapeutic experiment with something of the discipline they would accept if they were participating in a laboratory experiment—planning, executing, and recording it systematically, and frankly surrendering a little of their clinical independence so that the rightness of the therapeutic hypothesis may be more surely tested.

Traumatic Paraplegia

During the late war it was the standard practice of British and American surgeons to perform an early suprapubic cystotomy for all cases of traumatic paraplegia. The paraplegic has therefore arrived at a special centre with a cord lesion and an open bladder wound. Riches[1] now believes that the primary cystotomy can be delayed 24–36 hours without fear of irreversible pressure effects on bladder or kidneys, *an interval within which most cases can now reach* a special centre. Guttman[2] goes further and believes that many paraplegics can be treated throughout without a suprapubic cystotomy, provided they reach the special centre for their primary treatment.

The paraplegic after primary treatment presents five major problems—the urological, the neurological, *the orthopædic-ambulatory*, and the dietetic, and the plastic problem of the decubitus ulcer. It is on the control of the urinary tract that the prognosis of life chiefly depends. The greatly improved methods of recent years are best reflected in the mortalities, which at most centres here have been about 5–10% over the first five years. In the war of 1914–18 the figure was nearer 40% The critical urological question is whether the patient should be condemned to a permanent suprapubic life. Riches has described the excellent results, in terms of watertight closure and freedom from *infection and stone*, which can follow a high suprapubic cystotomy with an oblique tract and a small tube. Nevertheless, the highest standards of social and economic rehabilitation are impossible while the patient is condemned to a suprapubic tube. In the U S.A the policy of Prof. Donald Munro at Boston has been more or less generally adopted in the Army paraplegic centres, where about 1200 of these patients have been treated. This school regards a permanent suprapubic as a confession of surgical failure Chiefly by the use of tidal drainage they aim *in each case at the institution of* an automatic bladder, without dribblings or residual urine. Those who have visited the paraplegic centres at Staten Island, Atlantic City, White Sulphur Springs, and Toronto, have reported that about 90% of the cases show this result, and are voiding urine per urethram. It is clear, too, that this policy of closure of the suprapubic drainage is not reflected in a higher mortality than has been obtained in this country. The mortality in the first year after reaching special centres in America has

been 1–2%.[3] There are some resistant cases which do not develop an efficient automatic bladder on tidal drainage, and in these cases, which show residual urine, well-marked trabeculation, and a trigonal fold across the internal meatus, the neck of the bladder has been resected. For the same type of case Lieut.-Commander HOEN, U.S.N., in Long Island, divides the anterior root of S.4 on one side to weaken the tone of the compressor urethræ. Both these procedures must still be considered experimental and awaiting full evaluation. The efficient application of tidal drainage for paraplegics is a most laborious and exacting procedure. For its routine and continuous use in large groups of patients over a period of weeks an exceptionally high standard of devotion in the medical staff at all levels is needed if the best results are to be obtained. But MUNRO and many others have now shown that most paraplegics can acquire an automatic bladder in two or three months by the thorough use of the tidal-drainage method, which not only can eliminate infection and check stone formation but in giving the patient voluntary control over micturition completes his reablement. The value of streptomycin against bladder infections is not yet settled. The antibiotic is undoubtedly effective against many of the common gram-negative organisms found in the urinary tract of these patients. However, during the first year of its use in the U.S. Army paraplegic centres many recurrences were reported, and acquired resistance in urinary organisms was often observed. Streptomycin must be given early and in very heavy dosage to be effective, and even then a single catheterisation can reinfect and undo the work of a whole course of the drug. Its chief value appears to be in the treatment of the acute infections or reinfections, when treatment must also be directed towards establishing and removing the primary cause of the infection.

The neurological problem comprises, in addition to the study of all the phenomena seen in paraplegia, the relief of pain and of spasms. Both here and in the U.S.A. intrathecal injections of alcohol have been shown to relieve these symptoms in selected cases. In perhaps one case in ten a chordotomy or rhizotomy may be indicated for the relief of persistent pain. The special value of a rhizotomy is that it permits a direct inspection of the cord lesion, which in some incomplete cases may be caused by pressure of bone or foreign body, the removal of which may effect a cure. In this war there were no reports of successful regeneration after the suture of divided caudal roots, or after the even more enterprising procedure of transposing dorsal roots above the lesion into the spinal canal and suturing them there to distal caudal roots.

It was a characteristic feature of the war's paraplegic casualties that they were more wasted than other wounded men. Their fall in weight seems to be chiefly the result of protein-loss, from the bedsores and the infected bladder. As much as 50 grammes of protein a day has been recovered from the dressings of a single large bedsore. Correction of the negative nitrogen balance is vital in the treatment of these patients. It is accomplished by intensive protein over-feeding. Up to 150–200 g. of protein may have to be taken daily for weeks on end. In this dietetic scheme concentrated milk-shakes play a large part. The beneficial effects of this generous diet are seen in every aspect of the patient's condition—in the urinary infection, in the healing of the ulcer and of the nerves, and in the patient's morale.

GUTTMAN, whose accurate descriptions of the gross anatomy and pathology of bedsores have greatly clarified our understanding of their progress and healing, stresses the adverse effect of the continued presence of adherent sloughs on the patient's general condition. He has drawn attention to the undermined edges, the sequestrating bone, and the burrowing sinuses with undrained pus pockets which are often seen, if looked for, in the early stage. At this stage ad-hoc surgery, for the removal of sloughs and sequestra and the adequate drainage of deep pockets, is essential; but radical reparative surgery may be disastrous if done before the patient's nitrogen balance has been restored, the edge of the ulcer has been sealed off by an epithelial response, and cultures have ceased to grow hæmolytic streptococci. The later alternatives in treatment of these ulcers are conservative dressings, free grafts, and repair by flaps of skin and fat. GUTTMAN has shown that, in favourable cases under expert treatment, moderate-sized ulcers can heal spontaneously in about three months. But many bedsores take much longer to heal, and all of those treated conservatively or by free grafts end up with a scar of thin epithelium on a dense fibrous base. This scar is commonly insensitive and unstable and must be protected for the rest of the patient's life. Such an end-result—at any rate when the ulcer is large—does not compare favourably with those obtained with big rotation flaps of skin and fat. At the Halloran Hospital on Staten Island, CROCE and his colleagues[4] in the U.S. Army covered sacral defects measuring as much as 18 × 12 cm. with local rotation flaps whose good vascularity and subcutaneous fat provided a more stable repair than could be obtained by natural healing. There is the further advantage that some of these flaps cut from sensitive areas may carry with them over the sacrum a degree of sensibility.

It is the object of treatment to make the patient independent of an armchair life. To do this walking is obtained by the use of crutches and braces. The lower the lesion the more trunk muscles are available and the more successful and stable is the gait, which may be either the "tripod" or "one-two" variety. But for walking with crutches to be possible at all power of grip must be present; C 8 must therefore be intact. The remarkable results obtained at Stoke Mandeville are illustrated by the fact that nearly half their patients have been discharged and half of these have found employment. Special training in such crafts as watch-making and photography is of particular value to patients with paraplegia. There is obvious value, too, in seeking, as has been done in the United States, the coöperation of the motor trade to make the adjustments necessary to enable the paraplegic to drive a car. With such cars driving lessons can become part of the reablement training at the special centre.

Few injuries present more complex therapeutic problems than paraplegia. Among war casualties the disability ranks next to blindness with loss of two limbs. Successful results by modern standards demand the integrated attentions of a number of specialists. The paraplegic centre must be under the clinical direction of one of these specialists—neurologist, urologist, or orthopædic surgeon—who must coordinate the work of the others in the treatment of the individual patient. This means that the centre should be sited at a hospital which has other special centres under the same roof, such as orthopædic, neurological, urological, or plastic. It is this organisation and the clinical devotion of the medical and nursing staffs, rather than any special form of therapy, which have yielded such successful results on both sides of the Atlantic.

Annotations

FOOD AND THE MINER

THE general policy of the Ministry of Food throughout the late war was to allow the maximum rations to all consumers rather than to give more to some at the expense of the remainder.[1] The special needs of heavy workers, such as miners and agriculturists, who have no access to canteens or "packed-meal" schemes, and so have to carry their midday meals with them to work, were partly met by a grant of extra cheese, and when bread-rationing was introduced last year these people received more bread units than the normal consumer. At the beginning of November, 1946, underground miners were allotted an extra ration of meat "in recognition of the efforts required to secure the maximum possible output of coal"[2]; and at the same time the allowance of meat to canteens was increased. These special rations are, of course, based on the fact that heavy muscular work uses up more food than lighter work, and that production is dependent on calorie intake. During the war the setting-up of industrial canteens and British Restaurants played an important part in maintaining health and output. These canteens made some discrimination in favour of the heavy worker, and there were two categories of rations, A and B, for canteens in heavy industries, both of which were more generous than that under which food was supplied to restaurants.

The Kaiser-Wilhelm Institut für Arbeitsphysiologie, to give it its full name, did some useful research at Dortmund before the war on the physiology of work, much of the expense of its upkeep being borne by the mining industry.[3] During the war, to avoid the bombing, the institute was evacuated partly to Bad Ems and partly to Diez. One of the many researches carried out by the staff has now been described by Kraut and Muller,[4] and this deals with the relationship between food and production, especially of coal. In the summer of 1943 rations in Germany had to be decreased far below the actual requirements. Kraut and Muller divided the calories contained in food into two groups—those necessary (1600–1800 per day) to maintain the body during strict rest, and the "work calories" needed for muscular activity of any kind. Experiments on a group of men building an embankment showed that output varied directly with the number of work calories in their rations. When a bonus of cigarettes was offered for increased output the relation between output and available calories was upset at once: the men lost weight in trying to do too much on the available food. A second investigation in 1943 was done on a group of 31 miners between 20 and 30 years of age. During a training period a daily total of 2800 calories, allowing 1200 work calo secured a daily output of 7 tons of coal per man— each ton of coal was equivalent to about 170 w calories. When given 400 extra calories a day the increased their output to 9·6 tons a day, but by t expending only 155 work calories per ton they los six weeks an average of 1·2 kg. in body-weight.[1] W they were given a further 400 additional calories output again increased slightly—to 10 tons per da and the men slowly regained their original weights.

The calorie consumption of coalminers in the R before the war varied from 3600 to 4800 a day, an the first year of the war the average daily ration 4200 calories. In the second year rations were cut the output dropped, though there was a time-lag be this result was observed. Kraut and Müller are convin that the fall in coal output was primarily due to t ration cuts. They maintain that each kind of w requires a fixed number of calories and that no acti can be continuously greater than the appropriate cal intake. If output is forced the workers lose weight this in itself lowers their capacity. A regular contro body-weight in industrial workers is a good meas of their calorie supply. Rationing of food, on this vi also means the rationing of industrial production.

An unpublished study of the diets of miners in vari British coalfields was carried out by the Ministry of F in 1944. This showed that underground workers w getting 3500–4500 calories daily. There have been more recent figures, and it is possible that increa mechanisation is reducing the miner's expenditure physical energy. A study of present-day diets body-weights might be illuminating.

GONOCOCCAL ARTHRITIS

IN considering obscure infective arthritis there is excuse for failure to exclude gonococcal infection by s simple tests as examination of an early-morning uret smear taken before micturition, and of the first u specimen of the day. Yet such tests are often omitt partly perhaps because it is not always recognised t the clinical and radiographic features of gonococcal rheumatoid polyarthritis may be identical. Some inter ing points emerge from a recent analysis of Service ca of infective arthritis by King and colleagues.[1] Exclud gonorrhœa, a quarter of the patients had non-spec genito-urinary infection. Involvement of a single jo was equally uncommon (less than 20%) in the gonococ and non-gonococcal cases. While the heels and plan fascia were affected with equal frequency in both typ gonorrhœa turned out to be the prime cause of infect Achilles tenosynovitis; arthritis of the metatar phalangeal joints was most commonly not gonococcal.

King and colleagues advise rest in bed for all patien whether febrile or not, and whether or not the affect joints are weight-bearing. Local heat is comforting, b splintage for more than a short period easily leads stiffness. Urethral irrigation is not yet obsolete in de ing with stubborn foci of infection, but prostatic massa must be practised with restraint and only after the su acute stage, since early vigorous treatment sprea infection. While the sulphonamides (and for th matter penicillin) did not prove very effective agai the arthritis, they were valuable, in combination wi fever therapy, in clearing up resistant genital infectio and were routinely used for this purpose. Artificial induced pyrexia, which is the great standby in deali with these joints, is most easily obtained by intraveno injection of T.A.B. vaccine; this is not without its dange and calls for skilful nursing, for it must be applied car and often, and the dosage pushed boldly to the limit

safety so that the bursts of fever follow closely with only a day or two of remission; transitory signs of liver damage are not uncommon. Of the patients receiving this treatment, 90% of the gonococcal and 69% of the other cases made a complete and permanent recovery.

Assessment of results with hyperthermy—mechanically induced hyperpyrexia—was more difficult because this method is usually reserved for late and resistant cases. The unit of dosage is eight hours at 106° F, preceded by two days of sulphonamide therapy. Of 130 patients who were given this treatment, about half had one such session and the remainder two or three. Each patient wears a B.L.B. mask throughout, breathing 5% carbon dioxide in oxygen during the induction, pure oxygen during the session, and the carbon-dioxide mixture again for two hours after the treatment. A litre of 5% glucose-saline was given routinely at an early stage of the proceedings. There was only one death in this series, but here again minor liver damage is not rare. The immediate response to the first dose, and the rapid restoration of function, are a great fillip to morale. It is sometimes difficult to decide whether recurrent joint irritability is due to persistent active infection or merely to the inevitable results of inflammatory damage. In this series 57% returned to full duty in their initial category, and 17% had to be down-graded. Of the 26% who were regarded as failures and discharged as unfit, many later made an excellent recovery in civil life. After several years 72% of the whole group of hyperthermy cases had made an excellent functional recovery; and though the recovery-rate was higher in the gonococcal than in the non-specific cases—76% as against 65%—the latter figure is high enough to hearten those who have been gloomy about the prognosis of chronic infective polyarthritis.

We may conclude that artificially induced hyperpyrexia of one kind or another is the treatment of choice for gonococcal arthritis and for metastatic arthritis from a non-specific genito-urinary focus of infection; T.A.B. vaccine, vigorously used, gives excellent results in the early stages, but hyperthermy is better for late and resistant cases.

DRYING PROTEIN

In a report to the Medical Research Council[1] Dr. Greaves discusses the technical problems met in drying protein materials, particularly serum and plasma, and describes the rapid growth of the M.R.C. drying unit at Cambridge during the war. A relatively simple "pilot plant," modelled on that of Greaves and Adair and producing 48 200 ml. bottles of dried serum a week, developed into one with a normal weekly output of 2500 400 ml. bottles of dried plasma, or in emergency twice as many. The experience gained in designing, building, and operating this large plant, which is now published as a whole for the first time, will be of great value to those engaged in similar work.

The degree of dryness achieved is of fundamental importance if proteins are to be properly preserved; but Greaves emphasises that, unless the containers used for the dried material are airtight, moisture may be taken up during storage and cause denaturation of the dried material, rendering it unfit for use. Thus dryness alone is not all: sealing must be perfect if preservation is to be satisfactory over any considerable length of time, especially in hot humid climates. Accurate observations on the storage qualities of dried-protein materials in relation to their initial residual moisture content, their storage conditions (especially temperature and humidity), and the length of time they are kept under these conditions, could not, unfortunately, be made during the overcrowded war years, and it is to be hoped that this gap will now be filled, so that one will then be able to forecast with assurance the "performance" to be expected from dried-protein material in any given circumstances.

Freeze-drying is the method of choice for preserving most therapeutic substances, and extension of its use in peace-time may be expected. Materials in the medical field which Greaves thinks are best preserved in this way include biological standards, therapeutic immune sera prepared in animals, immune and convalescent human sera, diagnostic antisera, human plasma for transfusion, unstable drugs, hormone preparations, bacteria, viruses and yeasts, vaccines, and human milk. Many of these substances are packed in small amounts, whose freeze-drying presents difficulties not encountered in drying larger quantities. Greaves concludes his survey by describing the "centrifugal vacuum spin-freezer" evolved to overcome these difficulties.

This is a worthy record of the technical progress made in the M.R.C. drying unit, under the stimulus of the war. The unembellished lists of figures representing the work accomplished by the unit give no indication of the anxieties, difficulties, and frustrations which had to be overcome before the plant got into its stride.

SOME LUTON FAMILIES

Luton is "a new, expanding industrial town, an urban island in a rural sea." It is also a town that takes its social problems seriously and shows enterprise in getting them investigated. Mr. C. G. Tomlinson[1] has added another good survey to those of Dr. Grundy and Mr. Titmuss and the various reports of the Luton school medical officer. Its interest is general in that the "social problem group" is carefully discussed.

Mr. Tomlinson distinguishes from his "problem families" three other groups who have come to grief: (1) "biological casualties," individuals or families who by reason of age or infirmity are unable to take proper care of themselves; (2) "social casualties," families whose efficiency and circumstances have greatly deteriorated because of the death of husband or wife, or because of the physical disability of the wage-earner or housewife owing to acute or chronic illness or too frequent pregnancies; and (3) "problem individuals," such as solitary migrants, prostitutes, habitual criminals, and delinquents. The true social-problem group he classifies as families who for none of these reasons "require a substantially greater degree of supervision and help over longer periods than is usually provided by existing social services." Thanks to this clear analysis his estimate of the incidence of social-problem families is much lower than any given by other workers, and the idea of the "submerged tenth" is dispelled by his figures. While he himself points out that London, South Lancashire, and other "reservoirs of human wreckage" may yield higher figures, in Luton at least, the proportion is more like a submerged hundredth.

The factors important in creating the problem family are, he finds, subnormal mental capacity, adverse family influence during childhood, broken families, absence of the husband in the Forces, alcoholism, and mental disharmony. In the 167 families studied these factors were found singly or in combination, or, in a small number of cases, coexisting with "social casualties." Mental disease as opposed to mental deficiency does not seem to be a causal factor. Only one case is mentioned in which a parent was admitted to a mental hospital, and in that case the family is said to have deteriorated owing to her absence rather than her illness. Moreover, most of the families exhibiting mental deficiency are not problem families; so that to be subnormal mentally is by no means a necessary first step towards becoming a social problem. The conclusion is that there is not really any distinct social group to be picked out: "On the contrary, the lesson seems to be that each problem family presents a unique complex of circumstances which can only be fully understood when regarded in its entirety." Encouraging though it may be to conclude that the incidence of problem families is low, nevertheless the absolute number, even in a relatively privileged town like Luton, is quite large enough to need some special measures.

[1] Preservation of Proteins by Drying, with special reference to the Production of Dried Human Serum and Plasma for Transfusion. By R. I. N. Greaves, M.D. *Spec. Rep. Ser. med. Res. Coun., Lond.* no 258. H.M. Stationery Office. Pp. 54. 2s.

[1] Families in Trouble. Charles G. Tomlinson, B.A. Admin., senior administrative officer, Public Health Department, Luton. Luton: Gibbs, Bamforth. Pp. 44. *3s. 6d.*

Mr. Tomlinson wants a combination of prevention and therapy. He favours voluntary sterilisation, though here he seems to disregard his own findings which provide little evidence of any inherited stigmata. The case for contraceptive measures rests on quite different grounds, and the inclusion of birth-control advice in the case-work organisation seems fully justified. Nursery schools, he thinks, can and do help to prevent fecklessness spreading from parents to children; and, however expensive these may appear, money spent on inculcating good habits and giving the child some experience of a happy life is soundly invested. On the therapeutic side, Mr. Tomlinson describes with admiration the work of the pacifist service units in Manchester and Liverpool, and appeals for more workers willing to attack the problem as they did—by going in person to scrub away the filth and mend and patch the derelict home and furniture. Anybody who undertakes constructive work for such people must recognise their "obtuseness of mind and degenerate habits" and to try to discover the means of overcoming the resistance that has already defeated innumerable attempts to help them. "To wash one's hands of those who do not respond willingly to the help which they are offered is to evade the whole issue and leave the worst cases untouched."

For its purpose *Families in Trouble* could hardly be better. It belongs to what has been called the Beatrice Webb school of medicine, and is altogether worthy of that school.

VITAMIN B AND BLOOD VELOCITY

THE circulation-time now has an important place in the assessment of heart-failure. The latest agent to be recommended for the test is the vitamin-B complex.[1] Its value for this purpose was discovered by chance through a woman to whom it had been administered parenterally complaining of a taste on her tongue like that of a "chewed-up vitamin tablet." The preparation consisted of 10 mg. each of thiamine hydrochloride and riboflavine, 5 mg. of pyridoxine hydrochloride, 50 mg. of calcium pantothenate, and 250 mg. of nicotinamide, dissolved in 5 ml. of sterile isotonic saline. House-officers and nurses who were given this preparation confirmed that the onset of the taste was abrupt, intense, and unmistakable. Descriptions of the taste ranged from that of a brewer's yeast tablet to one of stale fish with a warm sensation on the tongue and in the throat.

The test is carried out by rapidly injecting 5 ml. of the solution into the antecubital vein, and noting with a stop-watch the time between the beginning of the injection and recognition of the taste. In a control group of 50 healthy adults the average arm-to-tongue circulation-time was found to range from 9·8 to 10·3 sec. The figures for patients with heart-failure were: congestive failure without treatment (15 cases), 28–53 sec.; congestive failure controlled by digitalis (10 cases), 9·8–13·4 sec.; heart disease without congestive failure (10 cases), 9·9–31·0 sec. Few side-reactions were noted: 2 patients complained of epigastric fullness, 4 of feeling unusually warm, and 1 of bladder tenesmus twenty-four hours after the injection. The possibility of serious reactions in patients who are hypersensitive to thiamine[2] should however be borne in mind. Further work is being done to determine which component of the complex is responsible for the characteristic taste.

These results compare favourably with those obtained by other methods. Unfortunately, as with many other means of measuring circulation-time, the result depends on the patient's acuity; with an intelligent, coöperative patient the error is probably small, but with an ill or less intelligent patient there is bound to be a lag before he detects or indicates that he has detected the taste.

GERMAN INSECTICIDES

THE spoils that fall to the victors in a modern war are usually meagre; moreover, the vanquished enemy remains as a liability. All that can be extracted in the way of reparations seem to be some scientific secrets. The investigations of the Allied Intelligence Service have revealed some interesting research in the German chemical industry. The work on insecticides, like that in other fields, was uncovered in all stages from preliminary laboratory tests to large-scale manufacturing methods.[1] On the whole, chemical research was more efficient than the biological testing methods, some of which were rather crude.[2]

It seems that the Germans had known of the value of D.D.T. for some years and were experimenting in two directions—to simplify its manufacture and use, and to find a substitute which was not subject to Geigy's patents. A simplified mixture of D.D.T. analogues, about a quarter as insecticidal as D.D.T.[3] but easy to emulsify, was produced under the name 'Lausetο.' This was used extensively to proof clothing for the German forces against lice. In their efforts to find substitutes, the German workers tested a number of compounds chemically analogous to D.D.T. The most promising were 'Gix' (in which fluorine replaces chlorine in the *para*-phenyl positions) and 'Me 1700' or dichlor-diphenyl-dichlorethane; both have about a third to a sixth of the insecticidal power of D.D.T.[3] Me 1700, sometimes known as 'D.D.D.' or 'T.D.E.,' has been manufactured commercially in America, where tests have shown it to be highly toxic to mosquito larvæ.[4] On the whole, however, these analogues do not compete with D.D.T. in general utility.

Another type of compound which was shown to have high insecticidal powers was the organic sulphones. The dialkyl sulphones are very toxic to mammals as well as to insects, but the replacement of one alkyl group by an aromatic group gives a much safer, though no less insecticidal, compound. A number of substances of this type were tested, the most promising being, apparently, chlorphenyl-chlormethyl-sulphone,

which was given the name 'Lauseto Neu.' This is actually more toxic to lice and bed-bugs than D.D.T.; but it has the drawback of very low solubility in kerosene (about $^1/_4$%).[3] The Germans used it in the form of powders, dispersions, and emulsions; they were in any case so short of mineral oils during the war that little could be spared for insecticides. The value of these sulphones as insecticides deserves to be further explored; their toxicity to mammals must, however, be investigated before they are used here in practice.

In the absence of nicotine, the Germans evolved for agricultural use a substance known as 'Bladan,' the tive ingredient being the hexa-ethyl ester of tetra-hosphoric acid—$[(C_2H_5O)_2PO]_2PO$. This compound is, owever, believed to be less satisfactory than the natural roduct. In addition, a considerable number of organic trogen and phosphorous compounds were tested as secticides. Many of them were produced in connexion ith research on chemical warfare and are still on the cret list: none combines high insecticidal power with asonably low toxicity to mammals.

One programme was directed to discovering mosquito pellents, and, although the test method seems to have een rather crude, one very effective substance was ound and called '50/181.' This is trichloracetyl hlorethylamide ($C.Cl_3CO.NH.C_2H_4Cl$), whose effectiveess has been confirmed by S. R. Christophers in some ork which has not yet been published. The Germans sed it in the following formula: trichloracetyl chlorthylamide 7·5%, calcium chloride 1·25%, magnesium hloride 1·25%, absolute alcohol 60%, water 30%. It is aid to be innocuous when applied to the skin, but this ould require further investigation.

BATTLES LONG AGO

Nowadays, if the water-supply or sanitation of a big own goes wrong for an hour or two the citizens feel that heir rights are being infringed, and say so in bitter letters o the press. Yet only a hundred years ago legislation o provide these amenities was held to be an attack on he liberty of the subject.

Mr. Asa Briggs has lately reviewed[1] the passionate lifferences which ushered in the birth of our public-health system. The filth created in our towns and cities y the industrial revolution was the main argument f Chadwick and his colleagues—Dr. Southwood Smith, Ashley the philanthropist, Bishop Blomfield, Viscount Morpeth, and many others—and their method was to nake the facts known. Chadwick published reports on anitary inadequacies and abuses, and reached the conclusion that by knowing the general lay-out of a town he could tell where the worst epidemics would occur; Southwood Smith found that "wherever the Commissioners of Sewers have not been, there fever is prevalent"; and in Sheffield James Heywood and William Lee told how, "with awful precision," they could detect by inspection alone the unhealthy parts of the town. Everywhere filth and squalor were associated with unnecessary deaths and murderous epidemics. Southwood Smith summed up the debasing effect on the human mind:

> "There is a point of wretchedness, which is incompatible with the existence of any respect for the peace and property of others; and to look in such a case for obedience to the laws, when there is the slightest prospect of violating them with immunity, is to expect to reap where you have not sown."

The facts could hardly have been stronger; and by 1848, when Morpeth was introducing the Public Health Bill, they were very widely admitted. But the fight had merely shifted ground: it was now a debate on methods. "There were interests everywhere that had a stake in dirt and disease." The Bill, criticised as un-English, was said to embody an alien principle of centralisation, to endanger local pre-eminence, to permit an objectionable assumption of power by the Government, to be more like a Russian ukase than an English Act of Parliament. Reports on the towns, it was said, were exaggerated (though the facts in *Our Towns*[2] published nearly a hundred years later make it clear that they could not have been); the smoke clause would disable industry and make the manufacture of coke impossible; dirt, disease, and crime had no connexion with each other; water-closets had nothing to recommend them; and the whole thing was too expensive.

Mr. Briggs—though he himself resists the temptation—says we can hunt for parallels and differences if we wish. It is hard to refrain, for some of the arguments of the opposition have such a familiar ring. It is reassuring, at least, to know that one much-questioned innovation in the health field turned out so well.

MENTAL NURSING

If general nursing is facing serious difficulties at present, the situation of the mental nursing service is yet worse. Dr. A. Allan Bell, medical superintendent of Dundee Mental Hospital, recently reported to the city's mental-health committee that in the daytime he had only eight nurses looking after seven wards of 30–40 patients each; and that the nurse sometimes had to leave a ward wholly unattended while she took a meal. Many senile and sick patients in these wards cannot possibly receive the nursing attention they need.

Invited to send us his personal opinion, Dr. Bell praises highly the nurses who have stuck to their work under these trying conditions. Most of them have been in the hospital through the war, when overcrowded blacked-out wards increased the strain and anxiety of their work. This branch of nursing, he believes, is neglected because of the "prejudice, fear, and awe felt by the community against mental patients and mental hospitals." Even general-trained nurses share this prejudice; and he points out that though general nurses might profit by a period of experience in mental hospitals, that would not make mental nurses of them. The mental nurse has a different approach to the problems of mental disorder: "she has had her character so moulded and formed during her early years of training that no matter what her own particular personality may be she will continue to show the same sympathy and devotion to her patients, however difficult or aggressive these may be, thus displaying the value of well-organised sentiments in helping the emotional difficulties of others." It is interesting that Dr. Bell distinguishes this as a quality of the good mental nurse, and finds it undeveloped in the general run of State-registered nurses. There will be exceptions in both groups, naturally; but there is certainly some reason for supposing that this tenderness towards patients is more commonly fostered by mental than by general training; and yet it should be the chief attribute of every nurse.

In his staffing difficulty, Dr. Bell is turning to the new recruitment service started in Scotland under the Nuffield Hospital Trust; but as a long-term policy, he would like to see a well-planned regional mental-health service, each region having its own psychiatric administrator. The hospitals in the region would exchange staff, so that mental nurses, after training in a mental hospital, would be drafted to observation wards, psychiatric wards of general hospitals, child-guidance clinics, centres for the care of the aged, mental convalescent homes, and reablement centres. They would be of special value in the field of social psychiatry, and some might perform the history-taking duties of psychiatric social workers (who are almost unobtainable). They could certainly do much for the families of mental patients, helping them through difficult periods with recovered members, and encouraging them to seek early treatment when signs of breakdown threatened.

The next session of the General Medical Council will open on Tuesday, Feb. 25, at 2 P.M., when Sir Herbert Eason, the president, will take the chair.

Reconstruction

ORGANISATION FOR OLD AGE

AN INSTITUTE OF GERONTOLOGY?

TREVOR H. HOWELL
M.R.C.P.E.
LATE DEPUTY SURGEON, ROYAL HOSPITAL, CHELSEA

The present arrangements for the care of the aged sick are inadequate. All over the country doctors and social workers echo the question, " What can we do for our old folk ? "

Once this was a problem for the relations only ; now it concerns the whole community. Medical practitioners are anxious to get elderly patients into hospital ; medical superintendents want to discharge them and free beds for other cases ; almoners seek homes, domestic help, or nursing care for those no longer able to look after themselves. Outside the hospital sphere social workers, welfare committees, religious bodies, and charitable organisations make patchwork attempts to cater for the growing number of old people. Yet, in spite of all these efforts, the care of the aged sick and infirm remains unsatisfactory. Organisation against old age is long overdue.

WORK IN HAND

First let us consider some of the societies interested in this matter. On the purely medical side pride of place must be given to the Club for Research on Ageing. This body, whose members are scientists or doctors, is occupied with fostering research and investigation into senescence. Gerontology in the abstract is the chosen field for its labours. Its approach to old age is impersonal and not concerned, except incidentally, with the human or social aspect.

When we turn to the care of sick persons, most of the work is done by general practitioners, who gradually acquire considerable skill in geriatrics. Unfortunately, little of this is transmitted to younger generations, most of it dying with the doctor. During recent years the municipal " chronic " hospitals have undertaken the care of large numbers of old people ; but, according to the hospital surveys, few of these are comparable in efficiency with the average general hospital. In fact, the Institute of Almoners paints a gloomy picture of the conditions existing in some of them. The voluntary hospitals, which do not cater for the long-stay case, treat relatively few elderly patients.

It seems, therefore, that there is a great gulf between those who perform research into problems of senescence and those who look after the aged sick. The needs of the one are unknown to the other, and research is rarely carried out in hospitals for chronic sick. At the same time, the unrecorded clinical wisdom of the practitioner is lost. Hence little advance has been made in this branch of medicine during the last fifty years. It may be said of geriatrics that " the harvest truly is plenteous, but the labourers are few." There is need for more interest in the diseases of old age, more teaching of geriatrics, and a higher status for those who work in this sphere.

To bridge the gap between the medical and social aspects of gerontology, we have the work of the Nuffield Foundation. This promotes research on the one hand and collects social-welfare data on the other. Its beginnings in this field are full of promise. As the one organisation with adequate funds to perform its task, the Nuffield Foundation can be a fairy godmother.

Apart from this, there are numerous societies interested in the care of the aged. One of the most notable is the National Old People's Welfare Committee, sired by the National Council for Social Service. In the first place it promotes the formation of local old people's welfare committees all over the country. These perform very useful work and fulfil a long-standing need. Secondly, it is trying to coordinate the programmes of philanthropic and religious bodies which would otherwise compete or bid against each other for charity and public funds.

In the domain of housing, several schemes have already been put into practice. These vary from special municipal flats and cottages to colonies for the aged, such as the Whiteley Village Trust and the Victory and Churchill Homes of the Church Army. The Old People's Homes Committee of the Family Welfare Association performs valuable work, keeping in touch with various homes, hostels, and almshouses, and trying to find suitable vacancies for homeless old folk. A recent development has been the provision of hostels for the elderly who need more care and attention than they have in their own dwellings. Perhaps the best examples of these are the Hill Homes at Highgate, where some 150 old men and women live under sympathetic supervision in comfortable quarters. There has also been a renewal of interest in almshouses, and a new association has been formed in London to promote their well-being.

Another development is the formation of clubs for old folk, where meals and social amenities are available for a small subscription. The best known of these is the Darby and Joan Club at Streatham. For those who live in their own homes the Ministry of Health system of home-helps and the Women's Voluntary Services arrangements for the provision of ready-cooked meals are a boon and a blessing.

The organisations mentioned above are only a selection of those engaged in this branch of welfare work ; the National Old People's Welfare Committee has no less that 34 separate bodies represented on it. Therefore we cannot say that there is a lack of interest in the problems of old age.

DEFECTS AND DEFICIENCIES

When we come to consider the results of all these busy activities, defects and deficiencies begin to make their appearance. For instance, there is not enough provision for the infirm old person who needs nursing care or supervision at home. Lack of staff causes the nursing-homes either to refuse such cases or to charge high fees. The chronic hospitals consider them fit enough to be discharged, but they are not always equal to the task of caring for themselves. Home-helps and ready-cooked meals go somewhere towards their needs, but such cases are numbered by hundreds, not by tens. The Old People's Homes Committee does good work within its limits but gets swamped by floods of applications. The Church Army and other bodies interested in the provision of housing tend to work in relative isolation. The Institute of Almoners can act for patients in a hospital, but its knowledge and resources are not so readily available to the private practitioner. As yet there is no central bureau to correlate all the information and tap the various sources of help and expert knowledge. If a doctor or social worker is seeking assistance for some elderly person, it is often necessary to approach organisation after organisation, committee after committee, and secretary after secretary. First one and then another will plead shortage of funds, lack of accommodation, or a long waiting-list.

We see therefore, both in medicine and in social welfare, that there is a great shortage of facilities to meet the needs of old folks today, and that the existing organisations do not work together as they might. More homes, more hostels, and more hospital beds are wanted—more nurses, more doctors, and more welfare workers. Further, we must have contact between those who look after the elderly when they are well and those who care for them when they are sick. The coordination begun in the social sphere by the National Old People's Welfare Committee and the Old People's Homes Committee must be widened and extended to cover the realms of medicine and social service. In the United States the Gerontological Society attempts to perform this necessary duty as regards the scientific and economic aspects of old age, and the American Geriatric Society fosters an interest in the medical and nursing care of the aged. But a combination of medical, scientific, social, and economic efforts is needed if a real advance is to be made. There is a case for the foundation of an Institute of Gerontology in this country to relate the activities of all workers, medical or social.

AN INSTITUTE OF GERONTOLOGY

Let us consider how such an institute might be of service. In the first place, a central body would be able to extend the work of the Club for Research on Ageing and the Old Age Research Committee of the Nuffield Foundation. It could also organise teaching and encourage publication of original work on gerontology. Though there are now two American journals devoted to the subject, no British periodical of this kind exists. The issue of such an organ would supply a want long felt by those interested in old age. While knowledge of geriatrics was thus being disseminated through the profession, special hospital units could be set up in suitable centres. This suggestion was made by the authors of the Ministry of Health Hospital survey of the London Area and has much to commend it. In no other way will the care of the aged become an active, effective, and respected branch of medicine.

With research, teaching, literature, and practice thus encouraged, the social-welfare aspect of gerontology can be brought into line. There is at present an emergency bed service in London which can arrange urgent admissions to hospital on behalf of any doctor. With a similar central bureau, domestic help, convalescent homes, physiotherapy, and a bed in some hospital or hostel could as readily be found for the senile. Such an institute as that envisaged could make good use of the information already collected, hence only staff work would be necessary to give many old folk their freedom from fear. It seems a small price to pay for a very great blessing.

Some may think that an appeal for the foundation of an Institute of Gerontology is premature. After all, the subject is comparatively young, and only a few doctors are interested. In less than two years the new National Health Service is likely to be operating; hence some think that the Ministry of Health should be left to grapple with the problems and difficulties which have arisen. But these are the very reasons for prompt action. The young plant of gerontology must be watered and fertilised. All the present interest in the subject must be harnessed while it is still fresh. As for the National Health Service, it is a challenge to act while voluntary initiative can be effective. Before long, every new proposal will have to be referred to the mandarins of Whitehall. An organisation in being before 1948 would have a better chance of survival than one arising after that date. The need for it is urgent enough. At present the doctors' surgeries and the municipal hospitals' beds are choked with elderly patients needing help. Now is the time to act. Let us get ready to deal with the difficulties which beset old age. *Nunc floreat gerocomia.*

"... To find a truth and have it repudiated and neglected ... is one of the bitter things for the discoverer, and often an incalculable calamity for the world. In 1827, Melier, a young intern in a Paris hospital, expressed the belief that inflammation in the right iliac fossa depended upon disease of the vermiform appendix. He reported undoubted cases of appendicitis confirmed by autopsy. He described gangrene, perforation, concretions, and peritonitis. He ... believed that if the diagnosis could be made, operation was demanded. The great Dupuytren arose in discussion and destroyed that young surgeon."—Dr. EDWARD A. SCHUMANN in a presidential address to the American Gynecological Society (*Amer. J. Obstet. Gynec.* 1946, 52, 881).

PREFRONTAL LEUCOTOMY

REPORT ON 1000 CASES

IN 1945 the Board of Control started an inquiry into the results of prefrontal leucotomy. A questionary was sent to all county and borough mental hospitals in England and Wales, to all registered hospitals, and to most of the private mental institutions; from the replies received the board has published a report[1] on the results of this operation in 1000 cases of mental disorder.

THE OPERATION

In prefrontal leucotomy the frontothalamic tract, which connects the prefrontal area of the frontal lobe of the brain with the thalamus, is divided; and after this division the nucleus medialis dorsalis of the thalamus degenerates.

The crude intention of the operation, which was introduced by Egas Moniz in Lisbon in 1935, is to break the connexion between the patient's thoughts and his emotions, thus relieving mental tension and taking the sting out of experience. Emotional tension is an important symptom in many types of mental disorder, especially in melancholic and obsessional cases. The schizophrenic, though he appears unemotional, may be dominated by the emotion associated with his hallucinations and fantasies. It is for such cases that the operation is commonly used. The report notes that according to Freeman it can also be used to lessen mental distress from intractable physical pain.

Operative risks include death from hæmorrhage, immediately or later (19 cases in the series), or from a complication such as bronchopneumonia (4 cases), meningitis (3 cases), or cerebral abscess, respiratory failure, subdural hæmatoma, or empyema (each 1 case); the development of epileptiform fits or other postoperative symptoms; and changes of personality.

The surgeon cannot be certain of cutting the frontothalamic fibres.

> The report quotes a case, recorded by A. Meyer, of successful prefrontal leucotomy performed on a schizophrenic of 5 years' standing. This patient did extremely well, becoming happy and unworried; but when he died of carcinoma of the œsophagus 18 months later, autopsy revealed that the frontothalamic fibres had not been cut and the nucleus medialis dorsalis had not degenerated.

It is therefore possible that damage anywhere in the brain might have a beneficial effect in some cases; even so, as Meyer says, "it would be difficult to conceive of a theoretically and practically more rational place for the operation than Moniz has suggested."

STATISTICAL RESULTS

Of the 1000 patients 348 were males and 652 females. Cases were grouped broadly for statistical purposes under the following diagnoses: schizophrenia; manic-depressive insanity; neurosis, (*a*) obsessional, (*b*) other; postencephalitic states; mental defect; epilepsy; various.

Patients discharged recovered amounted to 24·8%, and patients discharged improved to 10·5%—making together 35·3% of cases treated. Among these, 9·3% relapsed. Patients who improved but remained in hospital amounted to 32·3%, and 3·7% of them relapsed. Only 1% were worse after the operation; 24·8% remained in hospital unchanged. Of 6% who died, only half (30 cases) died as the result of the operation; in 19 of these hæmorrhage was the cause. Fits were reported after

Medicine and the Law

Unlawfully Practising Dentistry

A MAN described as a "dental mechanic" was fined on each of three summonses for unlawfully practising ntistry, and was ordered to pay two guineas for costs, Frome petty sessions last month.

A witness gave evidence that she had a cracked upper ate and went to the defendant's shop where he fetched me plaster and took an impression; he told her that e charge would be £2 10s. She tried the new plate, it it was loose. He took another impression, but the sult was still unsatisfactory, and later two more npressions were taken. The solicitor who prosecuted behalf of the Dental Board explained to the bench at it is an offence under the Dentists Act, 1921, for a rson to practise dentistry if he is not registered in the entists' Register set up by statute. The 1921 Act pressly states that the giving of "any treatment, lvice or attendance as preparatory to or for the purpose or in connexion with the fitting, insertion or fixing of tificial teeth" shall be deemed the practice of dentistry. he defendant said he had been in the business for 33 ears. If the dentist had made the set correctly in the rst instance he would not now himself be before the ourt. He had tried to do a favour, and this was his ward. He claimed to have been a practising dentist 1921. This claim, of course, gave him no defence to e charges, as he had not taken advantage of the enerous provision under section 3 of the 1921 Act hich allowed the registration of persons who had been ngaged in the practice of dentistry as their "principal eans of livelihood" for any five out of the seven years receding July 28, 1921.

The case illustrates once more the statutory privilege hich Parliament has been willing to confer upon the entist, as also upon the architect. It is strange how ften the medical practitioner is accused of enjoying a ke monopoly.

Public Health

Scarlet Fever in Nairobi

SCARLET fever is rare in the tropics. In Kenya there ave been isolated cases; but no epidemic had been ecorded until last year, when Fleming[1] observed 19 ases in a European school at Nairobi; the illness was aild, and there were no deaths. Beta-hæmolytic streptoocci of group A were isolated from the throats of all the patients. The recent return of children from overseas, nd the consequent overcrowding of schools, may have ontributed to the outbreak.

Infectious Disease in England and Wales

WEEK ENDED FEB. 1

Notifications.—Smallpox, 0: scarlet fever, 1135; whooping-cough, 1890; diphtheria, 176; paratyphoid, ; typhoid, 6; measles (excluding rubella), 13,501; neumonia (primary or influenzal), 1278; cerebrospinal ever, 83; poliomyelitis, 12: polioencephalitis, 1; ncephalitis lethargica, 2; dysentery, 61; puerperal yrexia, 126; ophthalmia neonatorum, 52. No case of holera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from enteric or scarlet fever, 6 (2) from diphtheria, 2 (1) from measles, 13 (4) from whooping-cough, 92 (9) from diarrhœa and enteritis under two years, and 148 (23) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 215 (corresponding to a rate of 25 per thousand total births), including 30 in London.

In England Now

A Running Commentary by Peripatetic Correspondents

"THE good wishes of all go with them," says the account of the Royal departure. Most certainly this is so. After years of war-time restrictions and enforced insularity, the people of this country sail in fancy with the Royal family for the continent of sunshine and plenty, "the land of apricots and antelopes," where success waits upon the enterprise which freedom breeds.

The voyage to South Africa has excited extraordinary interest. Every stage of the preparations has been closely watched—the assembly of the fleet of cars, the shipment of the special train, and the rehearsals of embarkation at Portsmouth. We have read all the accounts, have listened to the broadcasts, and have shared in the excitement which the Princesses have enjoyed. The anatomy and physiology of the *Vanguard* is known to almost every man, woman, and child. Who does not admire Captain Agnew and the men he commands; who is not familiar with his cabin on the bridge, the galleys and guns, and the wardrooms and messrooms; who has not pried into the larders and pantries, and counted all those barrels of rum? We have even seen over the Royal apartments, and admired the loose covers and reading-lamps. We picture the family in their naval dining-room and know that they will fare well and enjoy their voyage. The bulletins of progress through the stormy Bay of Biscay were anxiously followed; now while they sail on under blue skies the happy music of the ship's band is wafted across to us in winter-bound Britain. Not only are we with them on the ship but we are awaiting them in sunny Cape Town.

Many of us would be glad to sail with them, perhaps to feel the sun once more after two almost summerless years, to taste again real food, not frozen and feigned but fresh and unfettered by coupons and points; or to escape for a while from a homeland of fuel crisis, austerity, and buff-coloured forms. Claustrophobia and insulaphobia are widespread. Who, if so bidden, would not hasten off to a convention in Europe, or make a tour of the American medical schools; who does not furtively glance at the advertisements in those adventuresome last pages of *The Lancet* and the *B.M.J.*, playfully imagining himself in the Dominions or Colonies living the full life under a smiling sun and a clear sky with a job to do and a fortune to seek? Lust for easy opportunity and adventure is compelling; in our flight of ambition we each shoulder the mantle of Cecil Rhodes and seek out the horizon.

* * *

When I was an A.M.O. at a private mental hospital there was a patient, a manic-depressive barrister, who took a dislike to me. When he saw me coming on my morning round he would half turn his face to the wall and address an imaginary court: "May-it-please-you-me-lud, gentlemen of the jury, this horrible monstrosity you see advancing towards you is indicted of the most terrible crime, to wit, of having . . ." The crime varied from day to day, but was generally of a kind not mentioned even by the Sunday newspapers. I used to stand and listen for a few minutes, fascinated by his eloquence and ringing scorn and by the amplitude of his facial expression—withering contempt, righteous fury, man-to-man satire, disgust. After a few minutes I would interrupt him, "Good morning, Mr. Doe," and he would turn to me with all the sunshine of his charm, "Ah, good morning, good morning, doctor, how are we today?"

I had an inside cabin on that troopship opposite the bathrooms. Nor did that enable me to get a bath when I wanted, all the chosen minutes between 7 and 8 were for the majors and colonels, and from 8 to 8.30 for the sacred ablutions of generals. In the hot weather they kept the door on the hook, which meant that I got their steam and another grievance, but there was one consolation—I could lie in my bunk and watch the reflexion of their faces while they shaved. Frowns and fury and the wrath of gods swept across those lathered countenances like gales on snowy tundras or thunderstorms on stubble. Sometimes they even articulated words like "blast" and "damn" and had to calm down to do the upper lip. Generally speaking, the higher the rank the greater the disturbance. I even took notes, contemplating a thesis for my M.S.A., "The Phenomenon of the Morning Hate." But what reminded me of Mr. Doe was that if the next on the bath list made expectant noises without, the sunshine immediately broke through: "Sorry, am I a bit late? Sorry, old boy. Shan't be a minute."

Why do I now recall these two episodes from the far and middle distant past? Because one who is near and dear to me this morning said, "Why do you make those funny faces when you shave?" "But, my darling . . ."

* * *

"Andrew arrived whole, hale, and hearty at 5.30 A.M. today. He inherits his mother's blood-groups—rhesus-negative—but thanks to his heterozygous father all goes well." So ran my message to a medical friend announcing my son's arrival. The reply may be helpful to my many colleagues who are struggling to master the rhyme and rhesus of this hæmolytic disease of the newborn. Scotland's expert vouches for its scientific accuracy.

Man Andrew, it would seem to me
Your homozygous mother
Has genes which must be cde,
While heterozygous father
Is CDe and cde.

Throughout your anxious pregnancee
They knew, poor devils, you might be
Small cde, big CDe,
Or homozygous cde.

If number one, there might be free
Agglutinins to big CD
Which might precipitate (oh gee!)
Erythroblastic tragedee.

Thank God your rhesus pedigree
Is cde and cde.

(I think your father must agree
To this genetic family tree
Before I add my Q.E.D.)

* * *

Perhaps I am wrong. I treat all my patients as intelligent people who can look at themselves objectively, and with suitable explanations I discuss all the aspects of their complaints with them. They are paraplegics resulting from the war. One of them, a Pole, of the highest courage and command of English, called me to his bedside while he was having a rigor. He asked me to put him into the next world. I discussed the pros and cons of euthanasia with him at length, and, having covered the religious and common-sense aspects, wound up with my own feelings and the legal position, finally stressing his lack of confidence in me should the request be a failure. At this point, he looked up at me and said, "Doc, you've got hold of the wrong end of the stick. I want to be moved into the next ward."

* * *

Listening to A. A. Milne's *Other People's Lives* on the radio set me thinking on its personal application. Being new in practice I wonder at the interesting medical conditions some patients harbour without complaint. "Never let them touch it, Missis," was Dr. X's advice 30 years ago to an elderly lady with a malignant-looking goitre. "My heart's never regular," says a chronic fibrillator, "I take a bit of digitalis when I feel dizzy." Should I alter the routine of these perfectly satisfied patients? Might I not turn them into medical successes but social failures?

* * *

Life's Little Compensations.—The Minister of Food has made an order to remove the price control of cherries. He also announces that the standards of strength of vinegar are the same today as before the war.

Letters to the Editor

SAUERBRUCH CINEPLASTIC AMPUTATION

SIR,—May I, as chairman of the meeting of th Standing Advisory Committee on Artificial Limbs, hel at Roehampton on Jan. 14, submit the following observations upon the article by Mr. R. K. Magee in your issu of Dec. 21?

Our committee appreciate the advantages which th operation, when successful, can give to the patient, bu there are certain drawbacks which have still to b overcome.

Cinematisation of an amputation stump was firs conceived by Dr. G. Vanghetti in 1897–98 after th return of Italians from the Italo-Abyssinian war. Following experimental work upon chickens the findings wer first put into practice in 1900 by an Italian surgeon—Ceci, of Pisa. Further work was carried out by othe Italian surgeons and later by Sauerbruch in German The possibilities of the procedure were not generall accepted until the 1914–18 war when it was again use more especially at several centres in Italy, and to som extent in Germany.

Several types of cinematisation have been suggeste each varying in the method by which function is produce in the prosthesis, and in the particular motive forc obtained from the musculature employed in the stum The better-known methods include:

1. *The club*—a projecting portion of bone or muscle, covere with skin and employed to activate and retain the prosthesis
2. *The loop*—formed by joining extensor and flexo tendons, covered with skin and similarly employed.
3. *The tendon tunnel*—somewhat similar to the loo method.
4. *The muscle tunnel*—a skin tunnel constructed throug the belly of a muscle; in this tunnel was placed an ivory pe to which the prosthesis could be attached, and by which could be activated.
5. *The pseudarthrosis motor*—a portion of the distal en of the bone in the stump being separated but having it tendons and musculature left intact to activate and contr the prosthesis.

Results of the work carried out up to this date wer given in Professor Putti's lecture, published in *The Lanc* of June 8, 1918, and in the *British Medical Journal* together with published articles by Dr. Vanghetti an others. It appears that the muscle-tunnel method gav the more satisfactory results. A few cases were treate in England by this method after the first world war, bu the results were for the most part unsatisfactory. Th operation was revived during the late war by Sauerbruc in Berlin, and by Leibsche and others in Munich.

Acting upon a recommendation of the Standin Advisory Committee, following a combined committe meeting with some American surgeons who had visite Berlin and Munich, the Ministry of Pensions sent delegation of surgeons and limb surgeons to Germany t investigate and report upon the results of this operatio and on the type of prosthesis supplied to the patient who had undergone this treatment.

On their return the members reported that Sauerbruch working in Berlin, was carrying out his original skin tunnel method, and that the prosthesis supplied had no materially altered in design or usage. In Munich a mor advanced technique was employed; the distal ends o the tunnelled muscles were freed from their insertions and this gave a greater range of movement, with mor power. The diameter of the skin tunnel had been considerably increased, allowing easier insertion of the ivor peg by the patient, and permitting better hygiene of th skin in the tunnel. Two well-known English surgeons witnessed the operative procedures on several patient at two centres, whilst a technical surgeon inspected th workshop where the prostheses were made and fitted.

A demonstration was given by about twelve patient who had been fitted with the usual prosthesis, the desig of which had not been improved upon. The greate number of these patients were afterwards seen in the workshop, where it was found that they had taken off the prosthesis to go home, saying it was rather heavy and irritated the skin tunnel after some usage. *Direct inquiries* ere made in many centres regarding the period for which prosthesis had been worn. how many skin tunnels had roken down, and how many patients had required eamputation. No records or data could be obtained.

The recent meeting of the Standing Advisory ommittee unanimously decided that before any ecommendation could be formulated it would be ecessary to produce a better-designed prosthesis. as the eight of the present apparatus was considered to be xcessive, while the artificial hand at present available as not satisfactory. The research department of the linistry of Pensions was instructed to give this work the ighest priority: some thought had already been given o the matter. and a prototype model of a prosthesis was hown to the members at the meeting. This model lemonstrated how the hand could be taken off the arm quite easily, and several of the normal appliances at present issued to amputees could be fitted to the arm. These appliances would enable the wearer to do finer work than was possible with the Continental type of non-detachable hand. The normal flexor and extensor ontrol would operate these appliances. Further work is being carried out, and the committee hope that with more efficient and lighter appliances a great range of function can be obtained from this type of reconstruction.

Liverpool. T. P. McMURRAY.

PERITONEAL DIALYSIS

SIR,—Dr. Fine's comments (Jan. 18, p. 120) are of interest and importance. He rightly points out that in the case we reported (Nov. 23) recovery was due to the diuresis which followed and was possibly the result of renal decapsulation. Unless any treatment of uræmia is followed by restoration of renal function it must be accounted a failure. If peritoneal dialysis is not to fall into disrepute there must be some hope of recovery in the cases selected for treatment. In our case the known removal of a small amount of urea (7 grammes) by peritoneal dialysis was followed by a sharp fall in the blood-urea level and great clinical improvement before diuresis set in. We cannot help feeling that even if double this amount of urea were removed and unaccounted for because of gross leakage of the dialysing fluid the clinical improvement of the patient justifies Dr. Fine's assertion that "measurement of urea excretion is only a convenient way of measuring the excretion of all diffusible retention products." The clinical improvement of our patient suggested that more than urea was extracted.

Dr. Fine and his colleagues have used continuous peritoneal irrigation in preference to intermittent rinsing. We have felt that when continuous irrigation is used a channel may easily form between the entrance and exit tubes, and but little of the peritoneal surface may be available for dialysis. In recent cases we have run 2 litres of fluid into the peritoneal cavity in 15 minutes, the fluid being retained for 2 hours and then drawn off. Analysis at short intervals shows that the urea content of rinsing fluid reaches that of the blood at the end of 2 hours. Using this technique we have extracted 30 g. of urea in 18 hours and have found that the urea content of the rinsing fluid may actually exceed that of the blood, an observation which has not yet been explained.

We believe that the main dangers of peritoneal dialysis in order of importance are first, gross interference with water metabolism and chemical balance of the body fluids, and secondly, peritonitis. Many cases of anuria are already waterlogged by enthusiastic hydrotherapy, and the use of improperly constituted rinsing fluid may increase the generalised œdema. On the other hand, as Mr. Rob and Dr. Richardson (Feb. 1, p. 195) point out, hæmoconcentration may easily be brought about, with results perhaps less devastating than those that follow rapid absorption of water. There is no reason to suppose that a rinsing fluid suitable for all cases at all times can yet be devised. and it is our opinion that adjustments should be made if indicated by clinical or biochemical study. We feel this to be an argument in favour of intermittent as against continuous irrigation.

In our cases peritonitis has not been prominent and penicillin has now been excluded from the rinsing fluid lest it have an irritating effect on the peritoneum, which by causing exudation might interfere with free osmosis. All the precautions recommended by Dr. Fine, however, must be taken into account. In some cases pain has been a prominent feature, and, rather than resort to morphine with its possible dangers in uræmic patients, we have used small quantities of 'Novocain' which have both a local and general effect.

With regard to the irrigating tubes, our experience runs parallel with Dr. Fine's—that rubber is unsatisfactory. Having tried steel we have recently used plastic polyvinyl, which is less uncomfortable, can be fitted more snugly to the abdominal wall, and is unlikely to cause dangerous pressure on intra-abdominal organs. The nature of the rinsing fluid may have more to do with the formation of adhesions than the chemical constitution of the tube. Much experimental work on the constitution, structure, and placing of the tubes, and on the nature of the rinsing fluid, still needs to be done.

While we believe with Dr. Fine and his colleagues that the peritoneum with its large surface is the ideal barrier across which to make intimate contact with the blood and body fluids, we are sure that Dr. Kolff's method deserves the closest attention by those interested in the treatment of uræmia by extrarenal dialysis. His method and apparatus, while brilliant in conception, seem to us cumbersome in application and therefore not likely to be universally adopted. The intimate contact with the blood-stream and body fluids which the artificial kidney and peritoneal dialysis allow has possibilities far beyond the treatment of uræmic states. Much experimental work and biochemical and clinical research must be undertaken before the method can be appraised and put on a footing safe enough for general adoption.

NURSING AND THE DOCTORS

SIR,—While it is true that nothing can make nursing one of the easiest of the many careers open to women today, some of us are doing all we can to eliminate old-fashioned discipline as far as the repute of the profession and the safety of patients allows.

But may I point out how often doctors are responsible for adding unnecessarily to the difficulties of the nurse's life? The morning and evening routine of washing and bedmaking, the serving of meals, and the tidying of the ward must go on whatever happens, and it is not helpful to have the medical staff invading the wards when every pair of hands is needed for these humdrum but essential tasks. (Incidentally, it is pointless for the Medical Research Council to condemn the practice of uncovering wounds within an hour after ward cleaning if surgeons insist on doing rounds before 10 A.M.) Rounds are often prolonged into the patients' dinner hour, or even begun then. The nursing staff is then depleted. some having gone to their own lunch, and often the upshot is that the ward sister forgoes her own meal to attend the doctor.

Surgeons who curse the nursing staff in the theatre and hurl their instruments about may relieve their feelings in this childish way, but courtesy and tradition prevent the nurses from retaliating in a like manner. Senior members of the medical staff who have the status and salary of lecturer to the nurses sometimes reel off the same discourse they give to their medical students, or cut their lectures at the last moment. Here is an example:

> At this hospital, about 25 miles out of London, attached to and partly staffed by a voluntary teaching hospital, a surgeon wished to give his lectures at 5 P.M. on the day that he operates. Since some of the nurses are on night duty I stood out for 6 P.M., so as not to curtail their sleep; and finally we compromised on 5.30 P.M. Learning at tea-time, one operating day, that the surgeon still had a partial gastrectomy to do, I asked whether I should postpone or cancel the lecture so that the night staff need not be called or the day staff spared from the wards. A message came back that the surgeon would be free by 5.30. The class assembled, some nurses who had had a day off returning from town for the purpose. At 5.55 P.M. the surgeon sent a message cancelling the lecture.

Certainly it is undesirable that nurses should have lectures while they are on night duty and on days off. but incidents of this kind help to make the recruitment of sufficient staff impossible; and lack of nurses means lectures in off-duty time.

Again, we can all sympathise with the wish of the doctors to open more beds, but while there are barely enough nurses to fulfil existing commitments it is unfair to add to their load, especially when they are living under conditions which should not be tolerated now the war is over.

In this converted mental hospital student nurses seconded from their London training school are sleeping in two-bedded cubicles with inadequate privacy, heating, and sanitary arrangements. The vast wards keep them occupied in domestic work for a large part of their day. There are no social or cultural amenities, and no transport to the station; and no attempt is made to compensate nurses for the cost of taxis and train fares to London, or to adjust their pay so that it is comparable, when such expenses are paid, with that of their colleagues in the parent hospital, where they too were accepted for training.

It is new for nurses to be articulate about their conditions, and it is of course inconceivable that they should resort to the strike as a weapon; but for that very reason they should not be exploited. Doctors could press for the block system of training; and by their manners and general attitude could acknowledge nursing to be not an ancillary but a complementary profession to medicine. We do not, of course, forget or fail to appreciate the many doctors who have been good friends of the nursing profession and faithfully served its interests in training schools and on committees.

A SISTER-TUTOR.

BODILY CHANGES DURING ABREACTION

SIR,—An alleged example of somatisation during abreaction was described by Dr. Moody in your issue of Dec. 28. In 1934 the patient, who was suffering from somnambulism with aggressive behaviour, had had his hands tied behind his back during sleep, as a precaution. On waking in a dissociated state he had tried unsuccessfully to free his hands. In 1944 this incident was abreacted under narcosis, when indentations resembling rope marks appeared on his forearms.

The detail given is insufficient to exclude the possibility that these marks were produced mechanically. Since the patient was under constant observation he might not have been able to use a rope; but marks resembling rope marks can be made by tightly pulled folds of cloth. The patient is said to have tossed and turned on the couch with his hands behind his back. If he was wearing sleeves, could he not have pulled them tightly round his arms without intending trickery? Folds of a sheet could also be used to make marks like those made by a rope. These possibilities are not mentioned in the account of the case.

St Benedict's Hospital, London, S.W.17. M. WALKER.

THE COST OF MEDICAL TRAINING

SIR,—Among other matters to be discussed with the Minister of Health about the new health service should be the cost of medical education. It is generally admitted that the sons and daughters of doctors are peculiarly fitted to follow their parents' profession, and it is anticipated (rightly or wrongly) that there will be a general reduction in the income of general practitioners, as well as a loss of capital associated with loss of the right to buy and sell practices. It is already a great financial strain on a doctor to educate his children at a university, and, unless the Government is prepared, at this stage, to express the intention of financing the medical education of suitable entrants there will be great reluctance on the part of general practitioners to enter the new service. We are not suggesting, of course, that such grants should be limited to the children of doctors; they should be open to all suitable candidates.

The Goodenough Committee reported that in the years preceding the war about £700,000 was paid to university medical schools by the University Grants Committee and local authorities. But local support to students is obviously unequally distributed in different areas, some local authorities giving very little to any university students; and medical students as such have very few special scholarships allocated to them. Many local authorities confine their grants to students from the authority's secondary schools. Unless there is a national scheme providing equal and adequate grants there will be an added difficulty in obtaining doctors to work in areas where their children's future is likely to be handicapped by poor educational facilities.

LYMPHOGRANULOMA VENEREUM

SIR,—Dr. W. E. Coutts (Dec. 14) gives some ver interesting information on this subject. He appears t suspect that this disease, together with Castellani' "endemic funiculitis," is related to the condition tha I described in 1941 as idiopathic thrombophlebitis, i that they are all due to the same virus. His reasonin seems to be on the following lines. The patients wit thrombophlebitis observed by Lieut.-Colonel Manson Bahr and Dr. Charters (Sept. 7) nearly all had venere disease; and their findings pointed to a virus infectio Therefore the virus is probably that of lymphogranulom venereum, which he believes to be associated wit thrombosis of the spermatic veins, the thrombosis i these two types of cases indicating a common causation

In my opinion Dr. Coutts's inference must be rejecte for the following reasons:

1. In Manson-Bahr and Charters's series the outbrea may have been due to transmission of an as yet unknow virus by syringe infection, as with infective hepatitis. A the patients were askari, and were almost certainly unde treatment.

2. I have seen more than two hundred cases of thrombo phlebitis, or tropical phlebitis as I prefer to call it, and i none of these was there clinical evidence of lymphogranulom venereum. In the few European cases I have on recor this condition could be definitely excluded.

3. Thrombosis is a complication of many unrelated disease and one cannot infer a causal relationship on this ground alone

I think Dr. Coutts will agree to the unique characte of the lesion when he reads Dr. Lendrum's descriptio of it in a paper which should appear during the summer

Luanshya, Northern Rhodesia. A. C. FISHER.

THE OUTLOOK FOR PHYSIOLOGY

SIR,—In his interesting lecture of Jan. 18 Prof. Lovat Evans touches indirectly on two points that seem to m to demand further consideration. First, why is not preliminary course in pathology given to preclinica students in the London hospitals as it is given to thos at Oxford and Cambridge? To arrive in the war knowing a few rudiments of disease processes must be distinct advantage to the new clinical student. Secondly why is pharmacology taught so early instead of being left to the period of clinical instruction? I submit that it is putting the cart before the horse to attend, for example, a lecture on the action of digitalis before one has eve entered a medical ward and seen its effects on auricula fibrillation.

In short, is not pathology taught too late in the curriculum and pharmacology too early?

J. B. GURNEY SMITH.

STAMMERING AND HANDEDNESS

SIR,—In view of racial differences in the incidence of stammering and the fact that I have not been able to find any published report of its incidence in Greece, I examined 1133 pupils of the Greek elementary schools of Nicosia, Cyprus; 574 girls and 559 boys between the ages of seven and fourteen years. There were 21 cases of stammering (1·85%): 5 girls (0·44% of the total children and 0·87% of the girls) and 16 boys (1·11% of the total children and 2·85% of the boys). The sex-incidence of stammering was 3 boys to 1 girl (16 to 5). Among these 21 stammerers 5 were left-handed. Not one of the right-handed stammerers gave evidence of left-handed tendencies. Among the non-stammerers 48 (4·2% of the total school population) were left-handed. They fell into three groups as follows: left-hand writers 9, ambidextrous writers 6, and right-hand writers with characteristics of left-handedness 33. There was no history of physical trauma or infectious disease as a precipitating factor in the stammerers.

From the average ages of their respective classes and from their teachers' reports the standard of intelligence of the stammerers was assessed as follows:

Above average	5 cases
Average	5 ,,
Below average	11 ..

The tendency to stammer appeared in all cases on attempting to pronounce *k*, *p*, *t*, and *f*: and in about a third of the cases stammering was caused on trying to pronounce *i* (with no consonant preceding or following). *r*, *m*, *l*, and *s*. By palpation of the epigastrium I found clonic and tonic spasms of the diaphragm in 14 cases. Other respiratory disturbances which I observed were reading and speaking during inspiration in 15 cases, hoarseness in 3. and shallow inspiration in 20. When the children read in unison with others, the stammering disappeared in 16 cases and diminished in 5. Tonic spasm of the lips was observed in 5 cases. movements of deglutition in 5, and movements of the whole body in 3. during reading and speaking.

All these investigations were made in the presence of normal pupils, in the usual atmosphere of the school-child. The teachers confirmed that all the children who stammered during investigation were stammerers in normal school life.

The incidence of stammering in these Greek-speaking Cypriot children (1·85%) is higher than in other European countries (Belgium 1·4%, Hungary 1·02%, Sweden 0·8%–1·0%) and in U.S.A. (0·87%). This finding contradicts the belief that the incidence of stammering is higher in races with a high cephalic index than in those with a low index, because in Greeks the cephalic index is low (Stephanos 1884, Gedeon 1931). Probably the differences in incidence of stammering among different nations are due to racial factors or to the difficulty in pronunciation of their languages. Thus, according to many investigators, stammering is unknown among the Chinese, whose language consists of monosyllables.

Nadoleczny (1926) found that the sex-incidence of stammering was 74 boys to 26 girls (3 to 1). My observations confirm this.

Travis (1931) reported many cases in which the stammering appeared as a sequel to the change of handedness; but in the present investigation 33 out of 53 left-handed children were at the beginning of their school life left-hand writers and changed to right-hand writers after training, without the slightest manifestation of stammering. This accords with the opinion of Seth and Guthrie (1935). However, there is a relationship between stammering and left-handedness, because the incidence of stammerers among these left-handed school-children (5 out of 53) is about ten times higher than among the right-handed pupils (1·5%). The explanation seems to be that left-handedness and stammering are two different manifestations which appear in a nervous child, neither of them causing the other.

Gutzmann (1928) found stammering in near relations of the stammerers in 26·8% of his cases, whereas Lampadarios (1923) reported 38·7%. I found it in 4 of my 21 cases; but in these cases the stammerer was in contact with a stammering relation (more often the father than the mother). So, possibly, stammering may be imitative rather than hereditary.

According to Seth and Guthrie (1935) the stammering occurs at all levels of intelligence but much more frequently among mentally retarded children. This statement accords with my observation that 11 of the 21 stammerers were of subnormal intelligence.

I wish to thank Dr. T. Dervis, O.B.E., chairman of the school committee of Nicosia, for permission to publish this letter.

VARICOSE VEINS

SIR,—I agree with Dr. Rowden Foote that varicose veins are a national problem. The figures in his letter of Jan. 11—the first figures, I think, published in this country—are startling: 5 million people in Britain incapacitated in some degree by a condition which in a large proportion of cases can be cured in a fortnight!

In these days of national drive for maximum production it is essential that this treatment be available. As Dr. Foote says, it is not realised that 1 in every 4 women over forty-five has varicose veins. (The proportion is not so high in men.) In the present state of the country, here is another opportunity for our profession to render a signal national service. These patients can be operated on and out of hospital in 48 hours, and back at work in a fortnight.

It seems to me that it is the duty of surgeons to show our profession that this is a fact, and to be ready to organise the necessary clinics for the diagnosis and the treatment. I suggest that the first step is for our teaching hospitals to set up separate departments for varicose veins and their complications in order to train men in their three aspects—medical (constitutional conditions such as anæmias, œdemas, and diabetes), dermatological (many patients first come to hospital with itching, dermatitis, eczema, and ulceration), and finally surgical, for the operations, injections, and various bandages.

When enough men are trained in this triple specialty, the other hospitals (or possibly the Minister of Health) can institute clinics staffed by this new type of specialist. Beds can be turned over three times a week (e.g., admission Sunday afternoon, operation Monday, discharge Tuesday noon, and repeat twice by Saturday noon). The treatment of varicose veins should not be relegated to the outpatient department or to the junior staff, but should be upgraded.

London, W.1. HAROLD DODD.

SOLUBLE SULPHONAMIDE COMPOUNDS

SIR,—In his letter of Jan. 4 Dr. Banks discusses the advantages of a soluble, neutral (and therefore non-irritant) sulphonamide. May we observe that in 'Albucid Soluble' (30% solution for intravenous injection) we present such a preparation? A solution of the sodium salt of sulphacetamide, this has a pH of about 7·4, and is thus non-irritant to the tissues. The high solubility and neutrality of buffered solutions of soluble sulphacetamide explain their efficacy in eye infections and inflammation of mucous membranes. When administered systemically, sulphacetamide has not so wide a range of therapeutic activity as several other sulphonamides, but its potency in some infections (e.g., *B. coli* infection of the urinary tract) has been established.

London, W.1. BRITISH SCHERING LTD.

EX-SERVICE ADMINISTRATORS

SIR,—The note of warning from your peripatetic *correspondent of Dec. 7 is all too timely*, and is emphasised by the news that a number of members of the Indian Medical Service will not continue to serve under the new Indian Constitution. Every private sympathy will be felt for our colleagues who have had planned careers upset by events beyond their control. Unfortunately, they will be returning to this country at a time when the policy of the land is to recruit a large number of medical administrators. Willy-nilly, the older men must be regarded as potential Bevan-fodder as Senior Officers Used to Handling Men.

As long ago as 1943 the talk of senior officers in the Services was of a Nice Little Job in the State Medical Service to eke out their pensions: now, in addition, comes the indication that in some things the leisurely gait of the Indian scene may colour our lives. For the demobbed the picture is familiar: the old reverence for red tape, the inevitable ignorance of conditions of general practice in this country, and (in many cases) the lack of opportunity for recent clinical experience is likely to give us a cautious and uninspiring administrative framework calculated to discourage and destroy any attempt to produce a wholly civilian service of a new and different kind.

of sufficient staff impossible; and lack of nurses means lectures in off-duty time.

Again, we can all sympathise with the wish of the doctors to open more beds, but while there are barely enough nurses to fulfil existing commitments it is unfair to add to their load, especially when they are living under conditions which should not be tolerated now the war is over.

In this converted mental hospital student nurses seconded from their London training school are sleeping in two-bedded cubicles with inadequate privacy, heating, and sanitary arrangements. The vast wards keep them occupied in domestic work for a large part of their day. There are no social or cultural amenities, *and no transport to the station*; and no attempt is made to compensate nurses for the cost of taxis and train fares to London, or to adjust their pay so that it is comparable, when such expenses are paid, with that of their colleagues in the parent hospital, where they too were accepted for training.

It is new for nurses to be articulate about their conditions, and it is of course inconceivable that they should resort to the strike as a weapon; but for that very reason they should not be exploited. Doctors could press for the block system of training; and by their manners and general attitude could acknowledge nursing to be not an ancillary but a complementary profession to medicine. THE OUTLOOK FOR PHYSIOLOGY

SIR,—In his interesting lecture of Jan. 18 Prof. Lovatt Evans touches indirectly on two points that seem to me to demand further consideration. First, why is not a preliminary course in pathology given to preclinical students in the London hospitals as it is given to those at Oxford and Cambridge? *To arrive in the ward* knowing a few rudiments of disease processes must be a distinct advantage to the new clinical student. Secondly, why is pharmacology taught so early instead of being left to the period of clinical instruction? I submit that it is putting the cart before the horse to attend, for example, a lecture on the action of digitalis before one has ever entered a medical ward and seen its effects on auricular fibrillation.

In short, is not pathology taught too late in the curriculum and pharmacology too early?

J. B. GURNEY SMITH.

STAMMERING AND HANDEDNESS

SIR,—In view of racial differences in the incidence of stammering and the fact that I have not been able to find any published report of its incidence in Greece, I examined 1133 pupils of the Greek elementary schools of Nicosia, Cyprus; 574 girls and 559 boys between the ages of seven and fourteen years. There were 21 cases of stammering (1·85%): 5 girls (0·44% of the total children and 0·87% of the girls) and 16 boys (1·41% *of the total children and* 2·85% of the boys). The sex-incidence of stammering was 3 boys to 1 girl (16 to 5). Among these 21 stammerers 5 were left-handed. Not one of the right-handed stammerers gave evidence of left-handed tendencies. Among the non-stammerers 48 (4·2% *of the total school population*) were left-handed. They fell into three groups as follows: left-hand writers 9, ambidextrous writers 6, and right-hand writers with characteristics of left-handedness 33. There was no history of physical trauma or infectious disease as a precipitating factor in the stammerers.

Apart from the unsuitability of the senior officer from the Service medical departments for the responsibility of administering a civilian medical organisation, it is well to inquire into the threat to the economic standards of the civilian medical practitioner. Retired officers are already in receipt of a pension designed to provide a suitable standard of living without other resources. This being so, their employment in the National Health Service, where they must inevitably act as a reservoir of cheap medical man-power, may be used by the Treasury as a lever to impose a lower scale of salaries on those of us who have to work for our living, and who need an appropriate rate of pay.

BURMA STAR.

SERVICE AND FREEDOM

SIR,—As it is often stated nowadays that in a Government service the independence of doctors must be crushed, their enthusiasm damped, and their merits ground down to a level of dull mediocrity, it is well to cite a few examples of the contrary.

Membership of the Indian Medical Service did not prevent A from bringing to the notice of the nearest military authority a glaring example of the suffering of the sick and wounded in Mesopotamia; nor did the threat of arrest by that authority stop him from neglecting all proper channels and going direct to a civilian who could and did take action that led to the appointment of the Mesopotamia Commission. That commission closed a black chapter in the history of the medical services, and laid foundations on which Maude and Marshall were able later to build their victories.

Nor did service in the I.M.S. prevent B from protest against a Government demand that he should operate on Mr. Gandhi in gaol—a protest so unanswerable that he was allowed to take Mr. Gandhi out of the gaol into his hospital.

If A and B did feel the curb, their independence had certainly not been crushed.

A Government service which, from an establishment of about seven hundred officers, produces three presidents of the Royal Society of Tropical Medicine and Hygiene, each of them a F.R.S., cannot be fairly accused of grinding its officers' merits down to a level of dull mediocrity. That one of these three embarked, as the cynics said, on the search for a third pension, but in fact upon a difficult and fruitful research into one of the long-hidden secrets of malaria, at an age when many are embarking for another, less fortunate, voyage, shows that Government service, even when prolonged far beyond the normal span, need not damp enthusiasm.

That stupid formality—I will not say stiff and starched, for his shirt was both—is inseparable from Government service is also a common statement, which my interview with the director-general, I.M.S., when seeking a commission, does not support. When he received me, the D.G.'s dress was a shirt and sock-suspenders; socks and trousers were added during the interview. Before his braces had been buttoned on to his trousers the D.G. said: "I'll have a wire sent telling you where and when to report." I'm pretty sure I have got the timing right, because he certainly had not put on his waistcoat before he shook hands and said goodbye.

This calls to mind a more historic incident, during the Indian Mutiny, when a young officer came without his sword to call on Sir Colin Campbell. Sir Colin, dressed in a towel, greeted him with, "Damn it, sir, you may come without your trousers, but you shall wear your sword." An incident which suggests that, even in those days of stocks and pipeclay, red tape had a high coefficient of elasticity.

Edinburgh. J. B. DE W. MOLONY.

TREATMENT OF TUBERCULOSIS

SIR,—I have no desire to enter into a discussion on the merits of amphetamine or as to whether the teachings of Trudeau and Marcus Paterson obtain better results than are achieved by surgical interference. It frightens me, however, to think what emphasis may be placed by tuberculous patients, some doctors, and perhaps the lay press on the utterance of a distinguished radiologist when he says (for the second time): "We also know that by far the greater majority of the people who contract *tuberculosis recover from it* without the disease being specifically treated or even recognised except by chance or mass radiography . . ."

Over many years, my patients have died of tuberculos or, with treatment, partially or wholly recovered. Some, I am sure, recover on their *own; but what multitudes* fail in this and enter hospital too late to receive material assistance. Can Dr. Brailsford (Feb. 8) be thinki of phthisis (i.e., postprimary progressive tuberculos of the lung)? If so, and if he can produce evidence f his statement, how eager we should be to have it.

But I suspect that by "the people who contra tuberculosis," he means the very many who undergo primary infection and in most instances recover from i except for the hard mineral elements which he is able see in his X-ray photographs. If so, I believe, wit respect, that he should by saying so avoid doing disservice to this particular cause.

Colindale Hospital, London, N.W.9. J. V. HURFORD.

BOVINE PLASMA FOR TRANSFUSION

SIR,—I should like to reply to your annotation bovine plasma[1] and the letters of Mr. Edwards[2] an Mr. Hughes.[3]

Colloid Osmotic Pressure.—Your annotation sugges that the osmotic pressure of prepared calf plasma (P.C.P is less than that of human plasma. With this Mr. Edwar agrees, stating that calf serum when heated to 100° exerts none, while Mr. Hughes thinks that heating w increase the osmotic pressure. Through lack of suitab apparatus I have been unable to follow the changes osmotic pressure during the preparation of P.C.P clinically, P.C.P. seems to exert sufficient osmotic pressu to remain within the vessels, and its administration hypoproteinæmic œdema is followed by diuresis. I not doubt Mr. Edwards's statement that plasma treate by his method and heated to 100° C loses its osmot pressure,[4,5] but my method differs from his in th amounts of formol and ammonia added. It would interesting if his experiments were repeated using m method of preparation.

Antigenic Properties.—From Mr. Edwards's letter an paper, heating to 100° C appears unnecessary, sin agglutinins and hæmolysins are inactivated at 72° This is agreed, but some antigenic properties are retain after heating at this temperature. With formolised ca serum heated only at 72° C it is possible to indu fatal anaphylactic shock in guineapigs, and to bri about anaphylactic reactions in man. Mr. Edwards do not report any anaphylactic accidents in his cas receiving despeciated bovine serum. I attribute th finding to the fact that few of his patients received mo than one transfusion of his bovine serum. Had he bee treating, instead of surgical cases, patients sufferin for example, from nephrosis or hepatic cirrhosis an requiring repeated transfusions at intervals of 5–7 day he might have observed typical anaphylactic crises, an obtained positive Prausnitz-Kustner tests.

I have evidence which suggests that my method ma not entirely preclude the possibility of an occasion reaction in man to P.C.P., but I am certain that, whi hypersensitiveness to repeated injections of bovi plasma heated only to 72° C is frequent, more than 10 ampoules of P.C.P., many of them given at intervals the same patients, have never produced a reactio of an undoubtedly anaphylactic nature: one reactio studied by me was due to sensitiveness to formol. I th feel justified in stating that P.C.P. is not antigenic.

Fate of P.C.P.—I do not know the fate of P.C.P. i the body. Occasionally slight albuminuria (sulpho salicylic acid test), lasting a few days, has been seen afte its administration. I consider it probable that most of is metabolised in the body, and I hope to investigate th problem.

Toxicity.—Mr. Hughes adds to the criterion "non toxic" a further criterion, the absence of the syndrom attributed to macromolecular substances such as gum acacia. I have not investigated this point. I can onl

2. Edwards, F. R. *Ibid*, p. 437.
3. Hughes, R. A. *Ibid*, p. 579.
4. Edwards, F. R. *Brit. med. J.* 1944, i, 73.
5. Gutfreund, H., Ogston, A. G. *Biochem. J.* 1946, 39, 186.

in 1934. On the histological side he produced noteworthy work on nævocarcinoma and on Paget's disease. Other useful contributions included his papers on erythema induratum, in which he discussed cases of this disease in middle-aged persons, his findings, with G. A. Harrison, on xanthomatosis, and his study of the Fox-Fordyce syndrome. Always looking out for something new, he demonstrated a form of impetigo due to *Demodex folliculorum*, and another form of dermatitis which he termed dermatitis colonica, and which he attributed to toxic absorption from the bowel.

Other appointments which came to Whitfield were those of professor of dermatology at the Royal Army Medical College, and dermatologist to St. Dunstan's. He was Lumleian lecturer at the Royal College of Physicians in 1921 and served as a councillor during the three following years. Both the French and Hungarian societies of dermatology elected him a corresponding member. Presidency of the section of dermatology of the Royal Society of Medicine in 1919–21 was followed by work as honorary secretary of the British Association of Dermatology and Syphilology in 1924 and as president of that body in 1927.

During all these years his energy and enthusiasm never flagged, despite a chronic and painful infirmity which often made movement difficult. This had undoubtedly been aggravated by his labours during the 1914–18 war when he helped his hospital by acting as general physician in charge of outpatients. This in addition to his appointment to the Prince of Wales Hospital for Officers, and evenings spent looking after the general practice of a great friend who had joined the Army.

"It is difficult," writes a colleague, "to name any one feature of his character as dominant, but unselfishness was one of his most prominent reactions to life. No trouble was too great to take when he found an enthusiastic class. Often his demonstrations were crowded by the presence of postgraduates from the Dominions and Colonies. To them he revealed the secret of his own success, for his first rule insisted on close and complete examination of the patient. With 'old patients' he was equally scrupulous, re-examining them time and again and always searching for new evidence which might modify his previous views.

"His wide knowledge of numerous subjects was a source of wonder to those listening to his expositions. The allied sciences were always studied carefully, and often he would suggest the wisdom of reading such-and-such a book on physical chemistry or on botany. The latter was perhaps his favourite hobby, and he spent many happy days as a practical gardener at his home in Beaconsfield. He was a good lawn-tennis player in his earlier life, and later enjoyed golf. But even in these games he was always questing for some physiological or anatomical or psychological reason for skill or lack of it."

Dr. Whitfield married Margaret, daughter of the late Charles Tuttle, of Rochester, N.Y., and she survives him. They had a son and two daughters.

RICHARD EAGER

O.B.E., M.D. ABERD.

Dr. Richard Eager, who died on Feb. 2, was born in June, 1881, near Ipswich, where his father was medical superintendent of St. Audrey's Mental Hospital. He was destined to follow in his father's footsteps, like him graduating at Aberdeen University and taking up a career as a psychiatrist. He took his M.B. in 1905 and his M.D. in 1912.

During the 1914–18 war he was a major in the R.A.M.C. and did important work at various neurological military hospitals on the psychological effects of head injury. He contributed various articles on the subject to the medical press, and their value was recognised when he was honoured with the O.B.E. In 1919 he returned to the Devon Mental Hospital where he had been an assistant medical officer since 1906. His war service had meant much to him and added a great deal to his professional knowledge, so that he was well equipped in 1922 to follow Dr. A. Davis as medical superintendent at Exminster.

As the head of a large hospital Eager showed his ability as clinician and administrator. His one passion was the welfare of his patients; it was both his career and his hobby, and nothing was allowed to stand in the way of what he considered was due to his patients. He set about modernising the hospital, equipping it with up-to-date plant and all that was needed to make it an efficient unit. This involved hard work and long hours, but he was doing what he wanted to do, and that for him was satisfaction enough. He was a pioneer in rehabilitation along the lines of occupational therapy, and he made his hospital one of the best-known for enlightened treatment. He was alive to the need for the early treatment of mental illness and believed that psychotherapy should be taken to the patients outside the hospital. Hence his keen interest in outpatient clinics and the establishment of one in the city of Exeter at a time when they were few and far between in the country. His passion for efficiency was manifested also in his desire for a highly trained nursing staff, and to this end he published his well-known *Hints to Probationer Nurses in Mental Hospitals*.

Eager spent fourteen years as a medical superintendent, every one of which was marked by his enthusiasm; so when he retired in 1936 as a comparatively young man it was inevitable that he should continue his life work in a private capacity. He joined the staff of the Royal Devon and Exeter Hospital as their first consultant in psychiatry, and built up a practice round his outpatient clinic. He retired only a few months ago.

Richard Eager had a forceful personality and a warm-hearted appreciation of his fellow men. He was kindly and obliging, especially to the young, whom he delighted to help. He was a popular superintendent, for he was fair and not afraid to champion the under-dog. His great characteristics were conscientiousness and tenacity of purpose. He carried out his schemes to their logical conclusions and nothing would turn him aside once he had set his heart on a certain line of conduct.

He loved good company and he will be missed by a large circle of friends who knew his quiet sense of humour.

He is survived by his widow, a son, and a daughter.

S. M. A.

RUDOLF JAKSCH

M.D. PRAGUE

Prof. Rudolf Jaksch, who died on Jan. 8 at the age of 91, belonged to the company of medical eponymists, for through his classical description of infantile pseudoleukæmia published in the *Wiener Klinische Wochenschrift* in 1889 this condition became known as von Jaksch's disease. English readers will also recall his *Clinical Diagnosis*, which was translated from the sixth German edition in 1907.

Born in Prague, he was educated there and at Strasbourg, and after taking his medical degree in 1878 he held junior hospital appointments at Prague and Vienna till he was appointed privatdozent at Vienna in 1883. Four years later he was called to Graz as professor extraordinary for children's diseases. In 1889 he returned to Prague as professor and director of the second medical clinic at the German university, and he held this post till he retired in 1925. His interests in medicine outside pædiatrics were linked with medical chemistry, and he published important papers on the chemistry of the blood and urine. After the first world war he dropped his hereditary title of Ritter von Wartenhorst.

DR. EDITH GHOSH

"Amid the horrors of the famine of 1943 in Calcutta," writes H. I. W., "Dr. Ghosh's house was a haven of solace and culture. Many British Servicemen, including myself, used to go weekly to meet friends and to hear glorious music. She never asked questions about us, but was always a gracious, friendly, and unassuming hostess. Most of us knew little more of her than this—that she realised the difficulties of life for us at the time, and did what she could to lighten the weight of those heavy days."

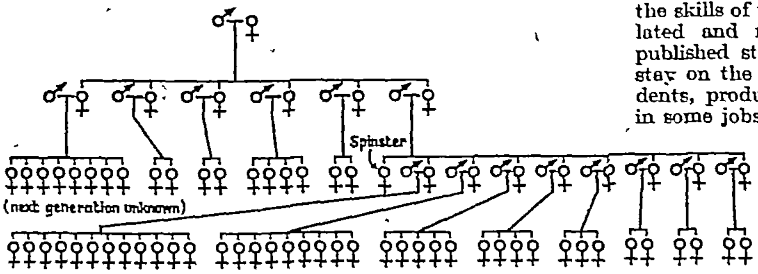
Notes and News

LADY TATA MEMORIAL TRUST

The trustees of the fund invite applications for grants and scholarships for research in diseases of the blood, with special reference to leukæmia, in the academic year beginning on Oct. 1, 1947. Grants of variable amount are made for research expenses or to provide scientific assistants to senior workers. Scholarships are awarded as personal remuneration: their normal value has been £400 per annum for whole-time research, with proportionate adjustment for work on a part-time basis, where this has been approved. The grants and scholarships are open to workers of any nationality, and in any country in which it will be possible to make payments in the coming academic year. Applications must be submitted before March 31, 1947, and the awards will be announced in June. Further particulars and forms of application may be obtained from the secretary of the scientific advisory committee, c/o Medical Research Council, 38, Old Queen Street, London, S.W.1.

MONSTROUS REGIMENT OF WOMEN

The sex-ratio in man is about 104 males to 100 females; but this figure naturally prevails only on a statistical plane. Small families commonly consist of sibs of one sex, possibly for a couple of generations or so, merely from chance. But Lienhart and Vermelin[1] have reported a French family in which 72 pregnancies produced 72 daughters in three generations. The genealogical table is incomplete, F3 not having been fully worked out (see figure). It is suggested that this is an instance of inheritance of an abnormality transmitted through the females, especially since none of the 15 husbands was consanguineous. But what is the abnormality? The first suggestion is that a lethal gene killed the male embryos at a very early stage (there is no history of abortion in the family); but this hypothesis is unlikely to explain the entirely female character of F2 and F3 (so far as it has been worked out). A second explanation is that the secretion of the genital passages or the constitution of the ovum is such as to cause death of spermatozoa carrying male sex. An experiment by Lienhart[2] seems to support this view. He treated rabbits' testes with X rays, with the result that the descendants were all does, suggesting that the Y chromosomes had been killed by irradiation. A third explanation may be based on work done by Vandel[3] on a species of crustacea (trichoniscus), some of which produce only males, others only females, and others both sexes. L'Héritier and Teissier,[4] working on drosophila, suggested that under certain experimental conditions the ova carried a "genoid" (F), which determined female sex. Consequently all the ova of the treated flies carried X (F), with the result that both the XX (F) and XY (F) gametes produced females. In the next generation an XY (F) female drosophila would produce two types of ova: X (F) and Y (F), the latter not being viable.



72 pregnancies producing 72 daughters in three generations.

It is well known that when both parents have a sex-linked abnormality all the children inherit it. But in the present family it is unlikely that the 15 non-consanguineous husbands had the same sex-linked abnormality as the great-grandmother. Haldane[5] has described *partially* sex-linked inherited characters, in which there is a strong tendency for all males to be abnormal and all females normal, or vice versa. In the present family all the gametes determining male sex might be so abnormal as to be non-viable. Haldane considered that the X chromosomes had two parts: one determining sex and carrying genes determining the recognised sex-linked characters, such as hæmophilia; and the other carrying the partially sex-linked characters, such as retinitis pigmentosa. One can imagine a further abnormality, so carried, preventing viability.

THE DISABLED IN AMERICA

In view of the recent report of our own care of the disabled[1] it is interesting to see how Americans are tackling the same problems. The rate of employment of physically disabled in the United States has more than doubled in the year since a campaign was started to make all these handicapped people self-supporting. In October, 1945, an Employ the Physically Handicapped Week was founded by Act of Congress to advertise the campaign, and last year a second week of the kind was held. There are some 28 million people in the United States disabled by disease, accident, or war, of whom about 2 million received their injuries in the recent conflict. It has been estimated that 1 in 7 of the male working population is disabled to an extent requiring vocational reablement or special placing. The Act establishing the national "week" invites the participation of governors of States, mayors of cities, heads of government departments, as well as leaders of farming, scientific, professional, and other organisations. Ninety organisations of national scope, with membership ranging from a few thousand to several millions, are coöperating in the drive to employ the disabled. The U.S. Employment Service maintains 1800 local offices, where the skills of the handicapped and the jobs available are tabulated and matched. The Civil Service Commission has published studies showing that the physically handicapped stay on the job better than others, have fewer serious accidents, produce with determination, expect no favours, and in some jobs are more efficient than people without physical defects. The commission's "Operations Manual for the Placement of the Physically Handicapped" is widely distributed, and during one week each year publicity devices are used to carry the significant facts home to the employer.

This government-sponsored campaign has been a greater success than was at first expected. During October, 1945, the first month of the campaign, some 11,000 handicapped people were employed; and in August of last year nearly 20,000 found work. Some 83% of the handicapped now being employed served in the recent war.

INTESTINAL EXPLOSIONS

It has long been known that the alimentary tract can produce explosive gas. Beatson[1] and McNaught[2] each mentioned a case in which a man's breath caught fire on blowing out a match, and Martin[3] and East[4] each reported a case in which a man belched while lighting his tobacco and singed his whiskers. The experimental ignition of flatus has also been practised. It is not surprising, therefore, that surgical electrical instruments have caused explosions within the intestinal canal. Lieberman[5] reported a case of explosion of intestinal gas during diathermy of a rectal polyp; and last year Moutier[6] reported to the Société de Gastro-entérologie de Paris that, as he was starting to perform an intrarectal electrocoagulation, and though he had taken the precaution of plugging the rectosigmoid junction, there was an explosion which caused the patient to collapse and gave her hiccups for a quarter of an hour. There was no tenderness of the rectum and no abdominal rigidity. Laparotomy two hours later revealed an extensive ecchymosis at the rectosigmoid junction. The patient recovered without sequelæ. In the discussion which followed, suggestions were made that, in such operations, the intestinal gases should first be aspirated, and that an improvement in design of the instruments should eliminate the risk of sparks. It was stated that a legal judgment had

previously been made in a similar case, the verdict going against the surgeon, and that therefore the patient or relations ought to be warned of the risk. It was also said that the explosive gas was not methane but a mixture of hydrogen and oxygen. In McNaught's[2] case the gas from the stomach was found, on analysis, to contain hydrogen 28%, air 9·2%, carbon dioxide 56%, and methane 6·8%.

Explosions can also take place inside the bladder. Kretschmer[7] and Hambleton et al.[8] have reported their occurrence during transurethral electroresection.

MORELL MACKENZIE

Mr. Scott Stevenson's book on the late Sir Morell Mackenzie[1] deals almost entirely with controversies centring on his treatment of the Emperor Frederick III of Prussia. He professes to give an authentic account of the whole unhappy story of this major episode in Morell Mackenzie's life, and does so fully and convincingly. It is a regrettable tale of professional wrangling, jealousy, and bitterness, on the whole best forgotten, but one from which the author thinks Mackenzie emerged with credit. From detailed analysis of the evidence he concludes that the accusations made by Mackenzie's German colleagues, also in attendance on the royal patient, and others, had no substance in fact. Mackenzie's first diagnosis certainly proved to be mistaken; but the mistake was an honest one. Though hasty and quick to resent reflections on his professional capacity, he was also generous and open-handed. It is a relief to turn from this unhappy story to his professional and social life at home. Here he earned the gratitude of patients by his skill and his understanding of those under his care. He founded the Hospital for Diseases of the Throat, and his treatise on diseases of the throat became a classic.

MEDICINE AND THE RENAISSANCE

"I HAVE no other means left for my maintenance but to turn physitian," wrote the poor monk dispossessed by Henry VIII. One of the early effects of the Renaissance in England was the Reformation, bringing with it the destruction of 110 hospitals. It was only on his deathbed that Henry VIII made the "comprehensive agreement with the citizens of London which led to his posthumous, if unmerited, distinction as first founder of the 'Royal Hospitals'." But Sir Arthur MacNalty, in the Thomas Vicary lecture for 1945, now published as a little book,[1] has better things than this to tell of Tudor medicine; and he does it with his usual thoroughness and grace. That time of plagues saw the beginnings of public health, thanks to the wisdom of such men as Sir Thomas More, Sir Thomas Elyot, and Dr. Andrew Boorde; and the revival of medicine began with the introduction of examinations, in London by the Bishop or the Dean of St. Paul's aided by doctors and surgeons, and in the provinces by the Bishop of the diocese with such expert persons as he might think convenient. Sir Arthur's account brings to life the vivid, human, cruel times, and the men who lived and worked then to found modern medicine.

TWO FILMS FROM AUSTRALIA

THE Scientific Film Association screened recently two films presented to them through the New South Wales committee in postgraduate medicine, with whom they are operating an exchange scheme. *Neurological Sequelæ of Deficiency Disease seen in ex-Prisoners-of-war* presents in simple manner a collection of cases received from Changi Camp. Examples of foot-drop, pot-belly, retrobulbar neuritis, nerve deafness, aphasia, and other disorders of motor and sensory nerves, of the types described in these columns,[1] are shown. (16 mm., sound, 27 min.)

Operation for Hydatid of the Liver is a first-class record in colour, showing clearly and without haste the outstanding features of an operation rarely seen in this country. Two small daughter cysts in the peritoneum are first removed, and then a huge liver abscess is cleared out. The two small cysts are opened, one being found to be dead and the other full of live hydatids; the small bladders are demonstrated, and then a single scolex is seen under the microscope. The commentary is good throughout, and the whole film a model of an unambitious operation record. (16 mm., sound, colour, 22 min.)

The New South Wales committee is collecting a library of medical films from overseas as well as encouraging home production. These two examples may lack professional polish, but they are far better than our amateur counterparts. The Australians seem to have achieved the happy mean between worthless records and highly expensive studio productions; we in Britain could learn a lot from them.

PLASTIC STOMACH-TUBE

Dr. FRANKIS EVANS writes: I can recommend a new type of Ryle's tube which is made of P.V.C. base plastic tubing. The ordinary rubber Ryle's tube can only be passed on a conscious patient, whereas the plastic tube is so made that varying degrees of rigidity can be obtained, depending on the temperature at which the tube is kept. At ordinary room temperature the plastic tube is sufficiently rigid for it to be passed into the stomach of the unconscious patient. This is of great benefit to both anæsthetist and surgeon. If the tube is to be passed on a conscious patient it need only be placed in warm water for a few minutes and it will be as soft and pliable as rubber. The tubes can be boiled repeatedly and show no signs of cracking or other deterioration. They have been made for me and can be obtained from Messrs. A. L. Hawkins, New Cavendish Street, W.1.

Royal Society of Medicine

No diary cards can be issued for the present, but meetings will be held as usual.

Royal Sanitary Institute

At a meeting to be held at the Town Hall, Llandudno, on Friday, Feb. 28, at 2.30 P.M., Dr. J. Glyn Jones will read a paper on Tuberculosis Under the New Health Services. On Friday, March 21, at St. William's College, York, at 2.15 P.M., Dr. Fraser Brockington will speak on the Work of Local Authorities under part III of the National Health Service Act.

Association of Surgeons of Great Britain and Ireland

The annual meeting of the association will be held at Oxford from July 3 to 5. The provisional programme includes a discussion on the Surgical Relief of Pain (excluding sciatica), to be opened by Mr. J. H. Kellgren, Prof. Geoffrey Jefferson, and Prof. J. Paterson Ross. There will also be a discussion on Ulcer and Cancer of the Cardiac End of the Stomach and Lower End of the Œsophagus, when the opening speakers will be Mr. P. R. Allison, Mr. T. Holmes Sellors, Mr. Vernon Thompson, and Mr. N. C. Tanner. Further information may be had from Mr. H. W. S. Wright, hon. secretary of the association, at 45, Lincoln's Inn Fields, London, W.C.2.

Penicillin Prescriptions under N.H.I.

The number of penicillin prescriptions under National Health Insurance was 52,850 last August, and incomplete returns for September show a rise of 4–5%, states Mr. A. W. Thompson, chief pharmacist to the Ministry of Health, in a bulletin to members of the Pharmaceutical Society. "As it is clear," he says, "that there will be more than 600,000 penicillin prescriptions during the first year, the additional cost to the Drug Fund must be over £70,000, unless the use of penicillin preparations substantially reduces the number of prescriptions."

Distribution of Drugs

Manufacturing chemists are perturbed by the terms of the Transport Bill, which affords them no exemption from the general ban on delivery by manufacturers' vehicles beyond a 40-mile radius. The manufacturers contend that drug transport is a skilled job, and that the ban will result in waste of time and space; they claim that drugs should be exempted as they were during the war and as meat is under the Bill. A deputation from the Wholesale Drug Trade Association was told on Feb. 6 at the Ministry of Transport that it was unlikely that complete exemption would be conceded; the Ministry thought that manufacturing and wholesale druggists would in practice have no difficulty in obtaining permits from the licensing authorities. The deputation expressed apprehension that there might be no uniform practice among these authorities.

Marcia Wilkinson
B.M. Oxfd, M.R.C.P.
MEDICAL REGISTRAR AT THE MAIDA VALE HOSPITAL FOR NERVOUS DISEASES

In this paper we describe 6 patients, all middle-aged or elderly women, who suffered from bilateral median neuritis due to compression of the nerves under the transverse carpal ligament at the wrist. They were treated by surgical division of the ligament. This operation appears to have been performed on only three occasions previously (Woltman 1941, Zachary 1945), and in those three patients the compression of the nerves was due to fracture or arthritis. In our 6 patients the compression arose spontaneously, but unaccustomed manual work may have helped to cause it. We have seen 8 other patients in whom the lesion has not yet been verified. Most of these add no fresh features, but allusion will be made to one, in whom the compression was secondary to fracture of the scaphoids and osteo-arthritis. The syndrome presents several points of interest in relation, particularly, to its pathogenesis, to the symptoms of slow compression of a mixed peripheral nerve, and to the diagnosis of partial thenar atrophy.

PREVIOUS OBSERVATIONS

Ramsay Hunt (1909, 1911, 1914) drew attention to syndromes which he described as "the thenar and hypothenar types of neural atrophy of the hand." The hypothenar type, which he ascribed to compression of the deep branch of the ulnar nerve, does not concern us further. He reported (1911) three examples of the thenar type. In two the wasting was bilateral, in the third unilateral. The limitation of the wasting to the abductor pollicis brevis, the opponens pollicis, and the outer head of the flexor brevis pollicis, together with the absence of sensory loss, led Hunt to place the lesion, hypothetically, in the thenar branch of the median nerve, which he supposed to be compressed where it passed over the palmar border of the transverse carpal ligament. Later (1914), however, he attributed the paralysis to a lesion of the thenar branch beneath the ligament. Marie and Foix (1912) reported ten examples of "isolated non-progressive atrophy of the small muscles of the hand," with four necropsies; but in only two of their patients was the wasting limited to the thenar eminence, and these were not among those on whom a pathological examination was made. Marie and Foix concluded that the lesion was in the spinal cord and was a localised destruction of anterior-horn cells, mainly of the 8th cervical segment.

A year later, however, Marie and Foix (1913) reported a case in which the lesion was in the median nerve.

> Their patient was a woman, aged 80, admitted to hospital with a cerebral vascular lesion and found to have also bilateral wasting of the *thenar eminences. Unfortunately, sensory* testing was impossible.
>
> Outside the central nervous system there was no lesion except in the median nerves, which showed, immediately above the transverse carpal ligament, a thick and firm nodular swelling or neuroma, while beneath the ligament there was a narrowing due to a "strangulation" which contrasted with the swelling above.
>
> Microscopically the swelling was characterised by great overgrowth of interfascicular and intrafascicular fibrous tissue, with destruction of myelin sheaths. At the level of the ligament there was still much intrafascicular fibrosis, but it was less marked than above. Weigert-Pal stain showed that the myelin sheaths diminished progressively from the upper limit of the neuroma and disappeared at the level of the ligament.

It was clear that the thenar atrophy in this case was due to an interstitial neuritis at the level of the ligament, causing a strangulation of the nerve beneath the ligament and a neuroma above it.

Brouwer (1920) reported 14 cases. His first 4 patients were tailors; 2 of his female patients did much washing, and 3 had arthritis. Brouwer emphasised the importance of occupation, and considered that the thenar muscles, being of recent phylogenetic development, were especially liable to undergo degeneration as a result of trauma.

Harris (1926) described wasting of the thenar muscles due to neuritis of the median nerve caused by intermittent pressure on the ball of the thumb by an instrument such as a trowel-handle or a scrubbing brush. He also mentioned wasting of the abductor and opponens pollicis as a result of motor neuritis secondary to arthritis of the trapezio-metacarpal joint at the root of the thumb.

Lhermitte and de Massary (1930) reported a case of senile non-progressive thenar atrophy, without sensory loss, associated with an atrophy of the posterolateral group of cells in the anterior horn of the 6th cervical segment of the spinal cord on the affected side.

Dorndorf (1931) reported 16 cases of isolated paralysis of the ball of the thumb. All his patients were women at or near the menopause. He was inclined to attribute the disorder to ischæmia, without reaching a conclusion about the site of the lesion. If it were in the median nerve, he thought the absence of sensory loss must be attributed to a higher resistance of sensory fibres or to a selective damage to the motor fibres.

Wartenberg (1939) reported 7 cases of "partial thenar atrophy." His paper included an anatomical report on the muscular branch of the median nerve to the thenar eminence by Saunders, who has found that this branch arises independently from the volar aspect of the median nerve beneath the middle of the transverse carpal ligament. It then proceeds distally beneath the ligament to its distal border, to pass through a definite canal in the lateral attachment of the ligament to the trapezium. After this it is reflected to pursue a recurrent course to its division to supply the individual muscles. In this part of its course the position of the nerve is variable in its relation to the flexor brevis muscle. Winckler (1930) has reported a case in which the thenar branch actually pierced the anterior carpal ligament. Wartenberg observes that these facts show that the thenar branches of the median nerve may be so unfavourably placed in a normal person as to be subject to trauma by the ordinary use of the hand. Nevertheless he concludes that the evidence that such is the cause of the thenar atrophy is unconvincing. The occurrence in some patients of paræsthesiæ not necessarily confined to the distribution of the median nerve suggests the presence of some unknown nocuous factor to which Wartenberg supposes the thenar muscles to be specially susceptible owing to their late development in the evolution of man.

Moersch (1938), who reported another case, accepted Hunt's view that the motor branch was injured as it passed over the distal edge of the anterior carpal ligament.

Woltman (1941) reported 2 cases of median neuritis with both motor and sensory symptoms. The first patient had acromegaly, and her hands eventually improved after X-ray treatment of the pituitary. The second patient had unilateral median neuritis, secondary to arthritis of the wrist, with motor, sensory, and trophic symptoms which disappeared after section of the transverse carpal ligament.

Zachary (1945) reported 2 cases similar to the last. His first patient had bilateral motor and sensory symptoms corresponding to the distribution of the median nerves in the hand, and X rays showed old fractures of both scaphoids, with osteoarthritis. The left median nerve was operated on by Prof. H. J. Seddon and found to be compressed in the carpal tunnel. An unexplained feature in this case, to which allusion will be made below, was loss of extension of the index and middle fingers. The second patient had an old malunited Colles's fracture and developed symptoms of median neuritis at the wrist more than twenty years later. Again the nerve was found to be compressed in the carpal tunnel, and paræsthesiæ and pain were relieved within two days of operation.

REPORTS OF CASES

I

A married housewife, aged 49.

History.—Three years ago she started to have a tingling and burning pain in the right hand, *involving mainly the thumb and 2nd, 3rd, and* 4th fingers. The pain did not extend above the wrist. At the same time her right hand felt numb. The numbness and tingling gradually got worse.

A year ago she noted wasting of the muscles at the base of the right thumb and also developed pins-and-needles and occasional numbness in the left hand. The pain was worse at night and on carrying anything heavy.

Past History.—During the war she had been doing an increased amount of housework.

Examination.—Right hand: wasting and weakness of abductor brevis and opponens pollicis and slight impairment to light touch and to two-point discrimination over the median distribution.

Left hand: slight weakness of abductor pollicis brevis. Slight impairment to pinprick and light touch over the palmar aspect of the 2nd and 3rd fingers, the loss to pinprick being more pronounced. Two-point discrimination: normal. Reflexes present and equal. No tenderness at wrist. No other abnormal signs in the central nervous system.

Radiography.—Cervical spine normal. Wrists, no abnormality detected.

Operation (August 1, 1946).—General anæsthesia. The right median nerve at the wrist was found to be enlarged and flattened above the carpal ligament, and was about three times the size of a normal nerve. A small vessel ran down the anterior side of the nerve, disappearing 1 in. above the carpal ligament. The bundles of nerve-fibres were separated by (? œdema) fluid, and in the carpal tunnel the nerve was thickened and swollen. There was no definite groove corresponding to the upper end of the carpal ligament.

Left nerve: similar in appearance to right nerve, but the changes were less well marked (fig. 1).

Follow-up.—August 17: subjectively there was a considerable improvement. She no longer complained of the burning pain and only occasionally had a tingling feeling. There was still some numbness of the tips of the fingers.

Feb. 3, 1947: no pain; occasional tingling in right hand, none in left. Hands feel stronger but no subjective improvement in sensation. Wasting and weakness of right abductor pollicis brevis less, otherwise no change in voluntary power. Sensation: right hand, no change in anæsthesia or tactile discrimination, analgesia limited to distal two-thirds of digits supplied by median nerve; left hand, slight hypæsthesia over median distribution, hypalgesia over distal half of index and middle fingers only.

II

A married tailoress, aged 37.

History.—Five years ago she noted that her left thumb was becoming weak, and that she could not button up her coat properly. Her thumb felt numb and cold, and she had some numbness of her 2nd and 3rd fingers. When she carried a heavy bag she had a feeling of numbness extending up her forearm to her elbow.

Three and a half years ago she noticed wasting of the muscles at the base of her left thumb. She attended a hospital and was told that she had progressive muscular atrophy.

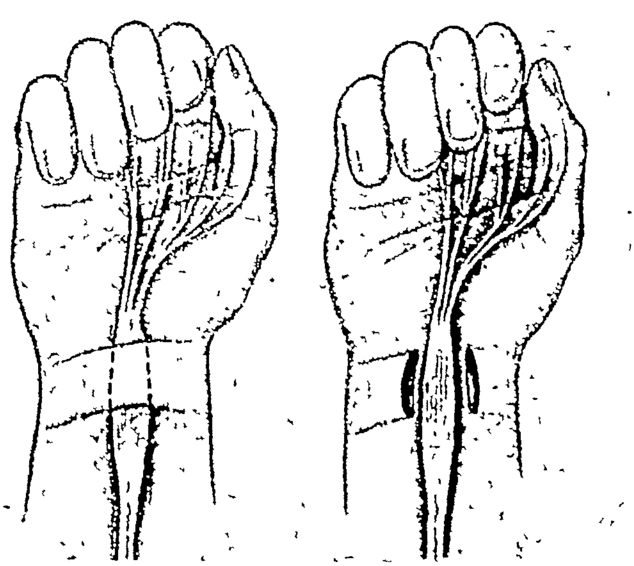

Fig. 1—Case I: median nerve flattened and enlarged under carpal ligament.

Three years ago the thumb and 2nd and 3rd fingers of her right hand became numb and the muscles of the right thumb wasted, and she had an itching feeling in her fingers.

For the past three years there has been no progression in her symptoms, but she still has pins-and-needles, numbness, and itching, and cannot sew because of the weakness and clumsiness of her thumb and fingers.

Past History.—On one occasion she was thrown to the ground by a bomb exploding close by, and she fell rather heavily on her outstretched hands.

Examination.—Well-marked weakness and wasting of both abductor pollicis brevis and opponens pollicis muscles. Slight hypalgesia and hypæsthesia over the thumb and 2nd and 3rd fingers of both hands. Two-point discrimination and joint sense normal. No other abnormal signs in the central nervous system.

Radiography.—Wrists and cervical spine: no bony lesion seen.

Operation (Sept. 19, 1946).—The left median nerve was found to be pale and swollen to about twice its normal size. The swelling extended for $^{3}/_{4}$ in. above the carpal ligament. The right nerve was also swollen but was slightly pink under the carpal ligament. In both nerves the nerve bundles could be seen distinctly. The carpal ligament was divided on both sides.

Follow-up (Jan. 23, 1947).—She had lost the feelings of numbness extending up the forearm to the elbow and had no pain or paræsthesiæ in the hand. There was still gross weakness and wasting of the abductor pollicis brevis on both sides, but power in the opponens pollicis on both sides was almost normal. There was slight hypalgesia over both hands of the same distribution as before, and an area of hypalgesia about 3 cm. in diameter on the palmar aspect of the left hand just distal to the end of the scar. Appreciation of light touch and tactile discrimination were normal.

III

A married housewife, aged 67.

History.—Six months ago she began to get a feeling of pins-and-needles in the tips of the 2nd and 3rd fingers of each hand. Later these fingers and the thumb became weak.

Five and a half months ago she was awakened at night with severe pains in the palms of her hands. These pains persisted and were always worse at night.

Five months ago the numb feeling spread from the tips of her fingers to the palms of her hands, and she was unable to hold or pick up small objects, such as needles. When she touched an object she got a pricking feeling in her fingers, although they felt numb. At night she had a burning feeling in her hands, and during the day her hands felt cold.

Three months ago she noticed that her hands were getting thinner.

Past History.—During the war she has had to do an increased amount of housework. No history of trauma.

Examination.—In both hands weakness and wasting of opponens pollicis and abductor pollicis brevis. No weakness of flexion or extension of the wrist. Hypalgesia, hypæsthesia, and impairment to two-point discrimination over distribution of median nerves. Slight defect of postural sense in the terminal phalanges of 2nd and 3rd fingers of the left hand.

No other abnormal physical signs in the central nervous system.

Radiography.—Wrists and cervical spine: no bony lesion seen.

Operation (June 11, 1946).—Both median nerves were exposed. The left nerve was swollen and pink for $^3/_4$ in. above the carpal ligament, and there was a depression on it corresponding to the upper level of the carpal ligament. The median nerve on the right side, which was also swollen, had divided into two parts about $1^1/_2$ in. above the upper end of the ligament.

Follow-up.—Two or three days after the operation pinprick was felt more sharply on the right hand, and there was a slight improvement in two-point discrimination. Subjectively there was considerable improvement, as the severe pain stopped and, though the fingers felt numb, the feeling of pins-and-needles diminished. Her nights were no longer disturbed.

Sept. 5: the feeling of numbness had shrunk to the distal half of the left index and middle fingers only. The wasting was less, and power had improved. Hypalgesia was present on the index and middle fingers and the terminal phalanx of the thumb. Hypæsthesia was present only over the terminal phalanges of the thumb, index and middle fingers, and tactile discrimination over the right index and left index and middle fingers only.

Nov. 6: she wrote that her hands felt much less numb, and that the movements of the thumbs were much stronger.

IV

A married housewife, aged 51.

History.—Twenty-one months ago she started to have a burning uncomfortable feeling in the index and middle fingers of both hands, which lasted for several months. After this she was free of all unpleasant sensation for five or six months.

Nine months ago she began to get a tingling feeling in the thumb and 2nd, 3rd, and 4th fingers of the left hand and the thumb of the right hand. This feeling gradually developed into a burning pain which affected the fingers but not the thumb.

Three or four months ago the same fingers began to feel numb, and the burning pain was brought on by using her hands. The tingling feeling was always worse in the mornings and more recently woke her up at night.

Past History.—In the past she has had several heavy falls on to her hands, but she has not broken any bones. In the last few months she has been doing an increased amount of housework.

Examination.—Wasting and weakness of both abductor brevis pollicis muscles. The short flexor of the thumb and the opponens pollicis were not affected.

Hypalgesia and hypæsthesia and slight loss of two-point discrimination in the distribution of the median nerve, the loss being more marked on the right than on the left. No other abnormal physical signs in the central nervous system.

Radiography.—Wrists and cervical spine: no bony lesion seen.

Operation (June 28, 1946).—Both median nerves were exposed at the wrist. On the right the nerve was pink and swollen for about $1^1/_2$ in. above the carpal ligament. The bundles of nerve-fibres could be seen distinctly. Below and more than $1^3/_4$ in. above the carpal ligament the nerve appeared normal. The left nerve was similar to the right and was even more swollen, being nearly as large as the sciatic.

Follow-up.—Two or three days after the operation there was a considerable subjective improvement. The tingling and burning pain went, but the affected fingers still felt numb.

After operation there was still impairment to pinprick and light touch, but this was less marked, and two-point discrimination was only very slightly impaired.

Feb. 3, 1947: no pain or paræsthesiæ. Fingers tend to go white in cold weather and puffy and shiny when very hot. Able to do housework, knitting and sewing normally. Just detectable wasting of abductor pollicis brevis on both sides: power in these muscles 90% of normal, and power in both opponens pollicis normal. No anæsthesia or analgesia; tactile discrimination perfect at 0·5 cm. separation.

V

A married housewife, aged 57.

History.—Two years' history of pain in front of right wrist spreading to thumb, index and middle fingers, like electricity, and associated with numbness in thumb, wasting of outer aspect of thenar eminence, and weakness of thumb. Four weeks' onset of pain and paræsthesiæ in left thumb, index and middle fingers. Left shoulder always higher than right. Occasional pain in neck on extension.

Examination.—Severe wasting and weakness of abductor brevis and opponens pollicis of right hand, and slight of left. Weakness of extension of right thumb at metacarpophalangeal and interphalangeal joints. Slight impairment of appreciation of light touch and pinprick over distal half of palmar surface of thumb, index and middle fingers, and radial half of ring finger of both hands and corresponding dorsal surfaces of terminal phalanges: no loss of tactile discrimination or postural sense. Sensory loss greater on right hand than left.

Electrical Reactions.—Faradic response lost in right abductor brevis and opponens pollicis, and sluggish in abductor longus and the extensors of the thumb on both sides.

Neck very short; extension somewhat limited; some pain on lateral flexion. Prominence of lower cervical spinous processes. Left scapula higher than right.

Radiography.—Dr. James Bull reports: "There are seven cervical vertebræ of which the atlas alone has a fairly normal appearance. C2 and C3 are fused and lack an intervertebral disk space between their bodies. C4 and C5 are fused and have a rudimentary intervertebral disk space. The same applies to C6 and C7. True intervertebral disk spaces are present between the pairs at C3–C4 and at C5–C6 level. The disk space between C7 and D1 is normal. Osteo-arthritic changes are present between C3–C4 and C5–C6. The body of C6 is rather rudimentary on the right side and causes a scoliosis. Bilateral cervical ribs are present at C7, the right being larger than the left. A very rudimentary cervical rib is present on the right side at C6.

"The right scapula is normal. The left scapula lies very high, the upper border being at the level of C7 (that on the right is at T3 level). The vertebral border of the left scapula, instead of having a normal straight edge, is angulated towards the spinal column in a V shape. At the apex of the V an abnormal bone articulates rather in the manner of the acromioclavicular joint. The abnormal bone has a spatulate appearance. It is triangular, with the apex directed cranially. The apex articulates with the spinous process of C5, the angle at the left base articulates with the left scapula as already mentioned, and the remaining angle of the bone is free. This triangular bone is about 8 cm. long and 7·5 cm. broad. It appears to be about as thick as a scapula and has a spinous process directed backwards at its upper end."

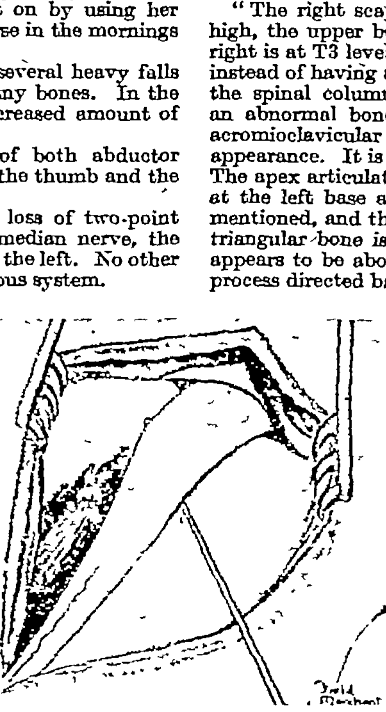

Fig. 2—Median nerve swollen and resembling a tendon.

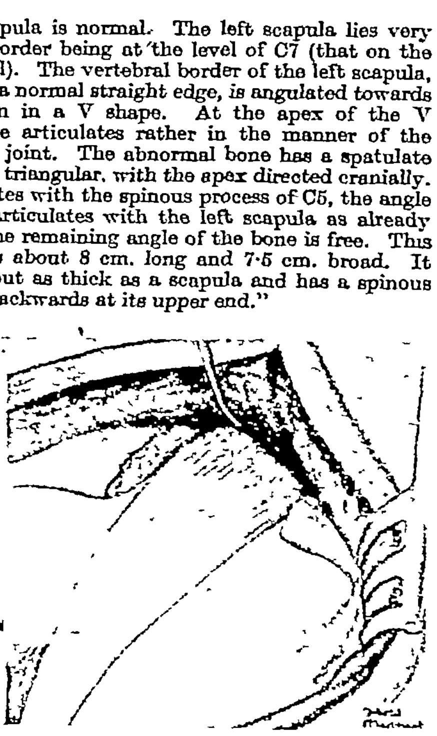

Fig. 3—Carpal ligament cut to expose median nerve.

Operation (Oct. 14, 1946).—The right median nerve was swollen for about $^1/_2$ in. above the carpal ligament and under the ligament. The carpal ligament was incised. The left median nerve was then exposed. This was also swollen but was pinker than the right. The left nerve divided into two parts about 1 in. above the upper end of the ligament, both parts running together under the ligament. The ligament was incised and the wound sutured.

Follow-up (Feb. 5, 1947).—No pain or paræsthesiæ. Power in thumbs stronger; can now darn for the first time for two years. Slight wasting of right abductor brevis pollicis, in which power is about half of normal. Muscular power otherwise normal in both hands. No substantial change in sensation.

Electrical reactions normal in thenar muscles of both hands except right abductor brevis pollicis which does not respond to faradism but responds normally to interrupted galvanism. Extensors of thumbs normal.

VI

A married housewife, aged 67.

History.—Three months ago while on holiday she did a great deal of unaccustomed heavy work. A few days later she developed a sharp shooting pain in her arms, which went down her hands. Every time she drew a deep breath she got a stabbing pain in the arm. The pain in the hand affected chiefly the 3rd finger and was always worse at night.

Six weeks ago she had some physiotherapy, which seemed to make the pain in her hands worse.

Five or six weeks ago both thumbs became weak and useless, the left being more affected than the right. She has noticed that the thumb and 2nd, 3rd, and half the 4th finger have felt numb, and she has a severe burning pain in her hands.

Right-handed.

Examination.—Hands: wasting and weakness of the opponens pollicis and abductor pollicis brevis, more marked on the left than on the right. Hypæsthesia and hypalgesia over the distribution of the median nerve. Joint sense and vibration sense normal. Two-point discrimination: no gross impairment. Reflexes present and equal. No other abnormal signs in the central nervous system.

Radiography.—Neck and wrists: no bony lesion seen.

Operation (Oct. 29, 1946).

Left hand: the median nerve was swollen and slightly pink. The surrounding tissues seemed more adherent than in a normal nerve. The carpal ligament was cut through.

Right hand: changes were similar to, but less marked than, those on the left. The carpal ligament was divided.

Follow-up (Feb. 5, 1947).—Feels much better. Free from pain except for occasional shoot in the fingers. Fingers still feel numb, but can knit and sew. Wasting of right thenar muscles less, but left unchanged. No change in voluntary power. Hypæsthesia of median distribution on both hands. Hypalgesia now limited to median supply to digits of right hand and on the left hand distal half of digits supplied by median nerve.

The clinical picture which emerges from these patients begins with burning and tingling sensations in the distribution of the median nerve of one hand. The discomfort may be severe and awaken the patient at night. Pari passu, weakness of the abductor brevis and opponens pollicis or, as in case IV, abductor brevis alone, develops, and these muscles waste fairly rapidly. Appreciation of pinprick, light touch, and tactile discrimination are impaired over the distal half of the fingers innervated by the median or even over the whole of the palmar aspect of these fingers. At this stage the pain diminishes, but sensory loss interferes with the manipulation of fine objects. Within an interval of weeks, months, or years the other hand is similarly affected. There is no weakness of the muscles innervated by the median nerve in the forearm, nor is the nerve usually tender at the wrist.

In all the patients operated on, the same lesion has been found: a compression of the median nerve where it passes beneath the transverse carpal ligament, and a swelling of the nerve for an inch or so immediately above this. When the history has been short, the swollen nerve has appeared pink; in more chronic cases it has seemed more fibrotic. It seems likely that the final condition in untreated cases is a neuroma, such as that examined histologically by Marie and Foix (1913).

PATHOGENESIS

The carpal tunnel (fig. 1) lies between the tough transverse carpal ligament anteriorly and the bones of the wrist-joint. It is divided into two compartments, the larger of which contains the tendons of the flexors of the digits and the median nerve, and the smaller the tendon of the flexor carpi radialis. Normally there is little spare room in the carpal tunnel, and it is easy to see how the median nerve may be compressed between the bones of the wrist-joint and the transverse carpal ligament when the tunnel is narrowed owing to fractures involving the lower end of the radius or proximal carpal bones, or to osteo-arthritis of the wrist. In our patients, however, no bony lesion was shown radiographically, and the source of the compression must be sought elsewhere. There can be little doubt that occupation is a causal factor. One of our patients, like four of Brouwer's, was employed in tailoring; four of the others said they had done much unaccustomed housework during the war; and in the last the onset occurred at a time when she had to carry buckets of water.

Abbott and Saunders (1933) state that, even in normal persons, acute flexion of the wrist pinches the median nerve between the proximal margin of the transverse carpal ligament and the anterior border of the distal end of the radius. They carried out injection experiments on the cadaver which showed that, if the wrist was in a position of acute flexion with some ulnar deviation, solutions injected proximally into the median nerve were arrested at a point opposite the proximal border of the transverse carpal ligament; whereas, if the wrist was held in moderate flexion or extension, the injections flowed easily into the palm of the hand and even along the terminal branches of the nerve.

Our own observations do not support the view that flexion of the wrist is the important factor. If the tip of the little finger is introduced into the carpal tunnel in the cadaver, it is easy to feel that there is much more room in it during flexion of the wrist than during extension. Moreover, on flexion of the wrist, as might be expected, the median nerve becomes slacker. To measure the pressure changes we constructed a simple tambour consisting of an elongated rubber-bulb, which was introduced into the carpal tunnel and was filled with water and connected to a manometer. The pressure was adjusted so as to register 0 when the wrist was straight. Flexion to a right angle raised the pressure to 100 mm. of water, but extension to a right angle raised it to well over 300 mm. of water. Measurement of the volume displaced showed that extension reduced the content of the bulb by 0·7 c.cm. as compared with flexion.

Acute flexion of the wrist is a rare movement, but extension is a common one, and repeated extension occurs in housework. In scrubbing and polishing, the hand holding the brush or the cloth is usually extended at the wrist, and the other hand often rests with the palm upon the flat surface and the wrist also extended. It seems that the rise of pressure in the carpal tunnel caused by repeated extension of the wrist is in some people sufficient to cause compression of the median nerve. Since most patients affected in this way are middle-aged or elderly, and since the pathogenic process in all pressure lesions of nerves appears to be ischæmia, it is probable that vascular degeneration in middle life increases the ischæmic effect of pressures which might be harmless in younger people. Moreover, the reaction of the nerve to pressure is œdema, which increases the pressure still further and so leads to a vicious circle.

The severity of the œdema above the constriction was surprising, but these observations in man confirm what has been found in the experimental animal. Weiss (1943a and b), in the course of experiments which involved the splicing of divided peripheral nerves by a cuff of live artery, noted that, when the splice was too tight, œdema developed in the nerve on the proximal side of the constriction, and thought that this indicated a centrifugal flow of lymph in the nerve which was obstructed by the constriction. Denny-Brown and Brenner (1944b) have observed a similar œdema after compression of a peripheral nerve with a spring clip. They reject Weiss's explanation on the ground that in his experiments the nerves were divided, and that the resulting interference with the circulation in the peripheral segment explains why the œdema was more severe proximal to the lesion. In their spring-clip experiments œdema was noted both above and below the site of compression. "Continued pressure on a segment of nerve," they write, "not only renders that region ischæmic but induces prolonged vascular stasis in neighbouring regions." After such lesions, as after tourniquet paralysis (Denny-Brown and Brenner 1944a), conduction in motor fibres is selectively damaged, and sensation, if impaired, recovers much more rapidly. The same authors (1944b) attribute this dissociation between motor and sensory function "to a functional property of the disorder of the axoplasm, and not to selective effect related to the size of the fibre."

Denny-Brown and Doherty (1945), in acute experiments on the effects of stretching peripheral nerves, found that after milder lesions a pseudoneuroma formed owing to the presence of fluid in the endoneural spaces, whereas when the lesion was more severe a true neuroma was present.

It is thus possible to give a fairly complete explanation of both the operative and clinical findings in our patients. The primary lesion appears to be a compression of the nerve as it passes through the carpal tunnel. The œdema proximal to the compression is comparable with that found experimentally above ischæmic lesions. This, if not relieved, tends to impair the function of the nerve and ends by becoming a true neuroma. The pathogenesis of this form of median neuritis is thus in some respects similar to that of the pressure neuritis arising in a "slipping" ulnar nerve, though the initial mode of compression is different. Meralgia paræsthetica, due to compression of the external cutaneous nerve beneath Poupart's ligament, is an even closer parallel. Since spontaneous recovery does not seem to occur, operation should be carried out as early as possible.

As Zachary (1945) points out, the selective damage to the motor functions, which led earlier workers to postulate an unverified lesion of the thenar branch of the nerve, is explained by our knowledge of the effects of trauma on a mixed nerve. Thus Stopford (1926) distinguishes three stages in the symptomatology of the compression of a mixed nerve: (1) increasing weakness and neuralgic pain; (2) objective sensory disturbance consisting of dissociated loss of appreciation of pain, heat, and cold before light touch, the neuralgia diminishing and disappearing as full analgesia develops; and (3) tactile anæsthesia within a smaller area than the remainder of the sensory loss. We have met with all three of these stages in our patients. Though weakness and wasting have on the whole been more severe than sensory disturbances, the latter have never been absent. Whereas it is possible that thenar atrophy may occur alone if the thenar branch of the median nerve is damaged in isolation, this hypothetical lesion has apparently never been proved to exist; and, in some cases regarded as examples of this lesion, sensory symptoms have been described by the patient—e.g., cases 1 and 2 of Hunt (1911). The frequent sparing of flexor brevis pollicis is no doubt due, as Zachary (1945) points out, to the fact that it is often innervated entirely by the ulnar nerve. When the palmar cutaneous branch of the median nerve lies superficial to the transverse carpal ligament it escapes; hence there is no sensory loss on the palm.

A feature which is difficult to explain is the presence, in two of our patients and in one of Zachary's, of weakness of some of the long extensors or flexors of the digits. Our case v showed weakness of extension of the right thumb and diminished response to faradism in the corresponding muscles on both sides. In one of our unverified cases both median nerves were compressed at the wrists as a result of osteo-arthritis secondary to fracture of both scaphoids. The patient had loss of flexion of the terminal phalanx of the left thumb, which he said had come on suddenly. Zachary's first patient had almost complete loss of extension of the left index and middle fingers. In our case v the extensors of the thumb recovered pari passu with the thenar muscles. We draw attention to this curious point so that others may look for it and perhaps discover the explanation.

DIAGNOSIS

When sensory symptoms are slight, the muscular wasting may suggest progressive muscular atrophy. The sharp limitation of the wasting to the outer half of the thenar eminence, and its severity there, in the absence of wasting elsewhere and of fibrillation, are characteristic, and the presence of paræsthesiæ and even slight sensory loss of median distribution exclude motor-neurone disease. Syringomyelia is not likely to lead to difficulty, for the characteristic dissociated sensory loss will usually be present and extend over an area wider than the distribution of the median nerve. Muscular wasting will not be limited to the thenar eminence, and the tendon reflexes will, as a rule, be diminished or lost in the upper limbs.

The diagnosis from the costoclavicular syndromes may be much more difficult; two of our cases had previously been diagnosed as such. Wilson (1913) first drew attention to thenar wasting as a symptom of cervical rib, and in particular to the occurrence of wasting of the abductor brevis and opponens pollicis with sparing of the flexor brevis. To explain this he assumed that "though their peripheral supply is from the same source, their root supply is from two sources, probably the seventh and eighth cervical. . . . It may fairly be concluded that the root supply of the abductor brevis and opponens pollicis is the seventh cervical, and of flexor brevis pollicis the eighth cervical." Wilson offered no proof of this, and there is an alternative and much more probable explanation, both of the wasting of the median muscles and of the sparing of the flexor brevis. Fibres from the C8 and D1 roots run to the median nerve through the inner cord of the plexus and the inner head of the median nerve. Compression of the inner head of the median nerve—e.g., by the third part of the subclavian artery—would involve the nerve-supply to the hand muscles carried by the median; and, as Highet (1943) has shown, in 80% of cases the flexor brevis is supplied by the ulnar nerve. Whatever the explanation, partial thenar wasting may be produced by a lesion of the median nerve in the carpal tunnel, or by a lesion of its thenar branch, or as part of a costoclavicular syndrome. Moreover, X-ray evidence of the presence of a cervical rib does not prove that this is the source of the wasting, since in our case v bilateral cervical ribs together with the Klippel-Feil syndrome and Sprengel shoulder coexisted with pressure neuritis of the median nerves.

Sensory abnormalities are therefore most important in diagnosis. They are relatively uncommon in the costoclavicular syndromes associated with structural abnormalities. In 60% of Sargent's (1921) 65 cases of cervical rib no objective sensory change was found, and in only 4 patients was sensation impaired on the radial side of the hand. The thenar type of wasting was present in 12 out of 32 cases. Thus it is clear that thenar wasting due to cervical rib is unlikely to be associated with sensory loss falling within the cutaneous distribution of the median nerve. When, as commonly happens, cervical rib involves either the C8 or D1 contribution to the plexus, or the inner cord, or the inner head of the median nerve, the segmental cutaneous area affected will be D1 or C8 or both. Even if the plexus be postfixed so that the C8 root carries sensation to what is normally the C7 cutaneous area, there will be no sensory change on the thumb or index finger. Objective sensory loss on the thumb or the index finger associated with thenar wasting is therefore most unlikely to be part of a costoclavicular syndrome and points to damage to the median nerve. Similarly, sensory impairment of full median distribution affecting the radial half of the ring finger and sparing the ulnar half can be caused only by a median-nerve lesion and not by a lesion involving the brachial plexus.

SURGICAL TREATMENT

The operation is carried out through an incision over the front of the wrist. The vertical incision is 2 in. long and precisely in the middle, and ends at the distal transverse crease, as it was felt that it was preferable not to make an incision over the flexor aspect of the wrist or to leave a scar on the palm. The nerve is practically subcutaneous and very easily found. Delay may be caused because of the altered appearance of the nerve, which resembles a tendon, as it is swollen to two or three times its normal size (fig. 2), resembling the friction neuromata seen in cases of cervical rib or attrition of the ulnar nerve at the elbow. In 2 of the 6 cases the nerve had divided about 2 in. above the carpal tunnel and passed through the tunnel in two thickened parts; this very common abnormality might also cause delay in recognising the nerve. It seems that there is an effort on the part of the perineural and endoneural connective tissues to protect the delicate nervous elements by thickening. The effect of this thickening is not helpful to the nerve, as it increases the friction and the compression even more so if this is a factor, as in the type of case we are now considering. It was demonstrated at operation that there is a considerable to-and-fro excursion of the median nerve in the carpal tunnel during wrist movements, but the thickening extended over much more of the nerve than the part chafed, the hyperplastic process extending some distance on each side of the irritated portion.

The anterior carpal ligament is cut through in the midline along its entire length (fig. 3) until the thenar muscles originating from its inferior border are seen and partly divided; the finger can then be passed through the tunnel with ease, to make sure that the nerve is free from constriction. The nerve is now lifted from its bed so as to demonstrate certain constant filmy adhesions, which are divided until the nerve is quite free, when it is returned to its bed and the wound sutured after securing hæmostasis following the removal of the tourniquet. No splinting is applied after the operation, and the wrist is only partly immobilised with a firmly bandaged wool dressing for seven days until the stitches are removed.

There is no reason to fear prolapse of the tendons, because all powerful movements of the hand are done with the wrist in extension. The physiotherapy appropriate to a peripheral-nerve lesion should be carried out.

RESULTS OF OPERATION

These patients have been observed for only a short time—from 3 to 7 months—since operation. Relief from pain and tingling was rapid and complete in all cases. No. iv has made an almost complete motor and sensory recovery in 7 months. No. v has made an almost complete motor recovery in $3^1/_2$ months without objective sensory improvement. The others have all improved to some extent, and improvement may be expected to continue until from 6 months to a year after operation.

SUMMARY

Six cases of bilateral compression of the median nerve in the carpal tunnel are reported. All occurred in middle-aged or elderly women without X-ray evidence of bony damage in the neighbourhood of the wrist-joints.

The symptoms were pain, parræsthesiæ, and cutaneous sensory loss within the distribution of the digital branches of the median nerves, and partial thenar atrophy, limited to the abductor brevis and opponens pollicis muscles or even the abductor brevis alone.

All were treated by surgical division of the transverse carpal ligament with immediate relief of pain and tingling and gradual improvement in power and diminution in sensory loss.

The lesion found at operation was compression of the nerves in the carpal tunnel, and œdema for about 1 in. proximally.

It has been shown that extension of the wrist raises the pressure in the carpal tunnel, and it is suggested that occupations involving this movement may in time lead to compression of the median nerves.

The symptoms and pathology are discussed in the light of recent experimental work.

Diagnosis, especially from costoclavicular syndromes, is considered.

We are indebted to Dr. Douglas McAlpine for allowing us to report case vi, and to Prof. J. D. Boyd, Prof. H. J. Seddon, and Mr. R. B. Zachary for helpful comments.

PURIFIED PRECIPITATED DIPHTHERIA TOXOID OF CONSTANT COMPOSITION

(P.T.A.P.)

Lewis B. Holt
M.Sc. Lond.

From the Inoculation Department, St. Mary's Hospital, London

Despite considerable advances extending over a long period, it has not hitherto been possible for the manufacturer to make any accurate prediction of potency, when assayed by in-vivo methods, of batches of diphtheria prophylactic, whether formol *toxoid* or alum-precipitated toxoid (A.P.T.). This lack of reproducible physiological activity has rendered unsatisfactory the assessment of immunising procedures, such as dosage, time intervals, &c.

The difficulties in the preparation of A.P.T. of uniform antigenicity arise principally from our limited knowledge of its exact composition, of the mechanism of the enhanced activity of the precipitated *toxoid* when administered as A.P.T., and of the influence of impurities on the induced antibody response. The position has recently been described by Glenny (quoted by Lewis 1941) as follows:

> "Any comparison between the efficiency of different prophylactics can only be made if many batches of the same type have been used, owing to the great variation in

the antigenic value between individual batches of the same type. The simplest type of prophylactic, formol toxoid, is subject to great variation. Glenny and Barr (unpublished) have found that the antigenic efficiency of two batches of diphtheria toxoid, of the same flocculating value and time, can vary at least a hundred-fold, as judged by antitoxin production in guineapigs. Large enough groups of animals were used to cut out individual animal variation. Methods of preparing A.P.T. introduce further variation: the type of medium used, the amount of potash alum added, and the subsequent separation and cleansing of the precipitate differ considerably in different laboratories."

This report is a summary of an inquiry into the nature of A.P.T. and of a method of preparing a new diphtheria prophylactic with an immunising activity at least equal to that of high quality A.P.T. and having a constancy of composition previously unattainable.

TECHNICAL

The first stage of the investigation was the preparation of the medium for the growth of the strain of *C. diphtheriæ* used. A slight modification of Mueller's (1939) semisynthetic medium was adopted which eliminated the variations inherent in digest media and gave toxins free from undesirable peptones and similar substances.

A study of the mineral composition of different samples of A.P.T. revealed that they were essentially a mixture of aluminium hydroxide and aluminium phosphate approximately in the ratio of bicarbonate to inorganic phosphate present in the formol toxoid.

It has been found, however, that both pure aluminium hydroxide and aluminium phosphate will precipitate the toxoid antigen; but whereas aluminium phosphate precipitates *only* protein, aluminium hydroxide also precipitates other nitrogenous matter. Finally, it was found that, if *purified* toxoid was added to a suspension of pure aluminium phosphate, the toxoid was precipitated in useful amounts.

Since this integrated preparation is a potent immunising agent (see below) it was important to be able to prepare the purified toxoid on a large scale. The refined toxoid used in this work was prepared by a method which will later be described in detail. It has a purity of 1200–1500 Lf/mg. nitrogen.

The purified and concentrated toxoid may be freeze-dried and stored for a long period. The dried material redissolves, apparently unaltered, on the simple addition of distilled water or saline.

PRELIMINARY POTENCY TESTS

When it was found that a suspension of pure aluminium phosphate would remove the toxoid from solution, it became clear that this could be the basis of an alternative method of preparing a diphtheria prophylactic without the disadvantages of alum precipitation, provided that the resultant product was a potent immunising agent.

A sample of pure aluminium phosphate was prepared with equimolar amounts of aluminium chloride and trisodium phosphate to give 3 mg./c.cm. of aluminium-phosphate suspension. To this was added sufficient concentrated and purified toxoid to give Lf 50, and the mixture was left standing for twenty-four hours. Examination of the preparation revealed that there was no detectable toxoid in the supernatant fluid, but that it was all in the centrifuged deposit.

A potency test was carried out with this preparation, using ten guineapigs (300 g. in weight) each receiving subcutaneously an injection of 1 Lf of the diluted preparation in 1 c.cm. of saline. The dose was repeated four weeks later, and the animals were bled six weeks after the first injection. A small quantity of blood was taken from each animal at the time of the second injection to observe the average antitoxin titre four weeks after one injection. The results were:

Titre after four weeks (one dose) ..	0·2 unit per c.cm. of serum (average value).
Titre after six weeks (two doses) ..	2·25 units per c.cm. of serum (geometric mean).

A duplicate test with another sample of purified and concentrated toxoid gave the following results:

Titre after four weeks (one dose) ..	0·2 unit per c.cm. of serum (average value).
Titre after six weeks (two doses) ..	2·05 units per c.cm. of serum (geometric mean).

Although not exceptionally good, these results were reasonably consistent and sufficiently satisfactory to warrant further investigation.

PROPERTIES OF PURIFIED TOXOID, ALUMINIUM-PHOSPHATE-PRECIPITATED

In the large-scale preparation of this new diphtheria prophylactic, with highly purified toxoid, and aluminium phosphate as precipitant and mineral carrier, several important points have to be borne in mind.

It is easy to add a measured volume of concentrated purified toxoid solution to a definite quantity of aluminium-phosphate suspension, and this operation may be regularly and readily reproduced. It is necessary, however, to ascertain what influence the following factors have on the potency of such preparations:

(1) Any damage inflicted on the toxoid during the processes of toxoiding and purification. For instance, an increase in the time required for flocculation with antitoxin (Kf) may indicate some damage inflicted on the toxoid.

(2) Purity of the toxoid solutions used. It is not yet practicable to produce the pure toxoid commercially. That used in the present method is about 66% pure. (The toxoid present in the initial solutions accounts for about 25% of the total protein or 2% of their total nitrogen contents.)

(3) Any influence of the amount of mineral carrier used per dose. Seal and Johnson (1941) have reported that an increased amount of alum precipitate does give rise to the production of more antitoxin in animals. These experiments were only roughly quantitative, and the observations were not further investigated.

The following information has been obtained on these points:

(1) *Prolonged Kf.*—Though the method of toxoiding used produces a toxoid with a Kf not exceeding three times that of the parent toxin, there is a *reduction* of Kf for the final purified solution compared with the initial formol toxoid.

(2) *Purity of Toxoid Solution.*—This important aspect of the problem in different samples of diphtheria prophylactic is being more closely examined. The new method of preparation makes it possible to investigate this point more accurately, as the amount of both toxoid and mineral carrier may be precisely controlled, leaving the purity of the toxoid preparation as the only variable factor.

(3) *Influence of Amount of Mineral Carrier.*—Briefly, the more aluminium phosphate injected per unit of toxoid, the greater is the antibody response in guineapigs, but there is an optimal amount, considerably in excess of that required merely to precipitate the toxoid, beyond which the response declines (see below).

STABILITY AND REACTIONS

It is also necessary to find out whether the new preparation is stable on storage, and whether it produces any untoward reactions in human prophylaxis against diphtheria.

Stability.—Samples of Lf 50, purified toxoid, aluminium-phosphate-precipitated, have been stored at room temperature for a year and have lost only 10% in flocculating power. A sample stored in the refrigerator for two years has shown no detectable loss.

In practice the new prophylactic can be made from purified and dried toxoid and freshly prepared aluminium-phosphate suspension as required.

Reactions.—Schick-positive children and adults have been immunised with the new prophylactic, and no untoward reactions were encountered.

Tests were also made on a few persons hypersensitive to diphtheria formol toxoid and to A.P.T. In these experiments a direct comparison was made between crude formol toxoid and purified toxoid, as well as between A.P.T. and purified toxoid, aluminium-phosphate-precipitated. The dose was 1 Lf each, in 0·2 c.cm. volume, injected subcutaneously. These injections were given simultaneously in strictly comparable skin areas. A reduced inflammatory reaction was definitely observed where the purified toxoid was injected, whether in solution or precipitated; therefore it cannot be claimed that no reactions developed at all. The aluminium-phosphate carrier without the toxoid gave rise to no untoward reactions.

POSSIBILITY OF A STANDARD DIPHTHERIA PROPHYLACTIC

For laboratory and statutory purposes it is desirable to have a standard or reference diphtheria prophylactic against which other preparations may be standardised, in much the same way as with some antitoxins, vitamins, and hormones.

The major difficulty in the use of A.P.T. as a standard has been its instability on long storage. Sir Percival Hartley (1945) has reported that freeze-dried A.P.T. has not proved satisfactory in this respect.

Though it cannot be claimed that the completed purified toxoid, aluminium-phosphate-precipitated, preparations remain stable indefinitely, this difficulty may possibly be overcome, as mentioned above, by using the two components separately: (1) the purified and dried toxoid, and (2) a suspension of freshly prepared pure aluminium phosphate. These could be integrated at the time of the potency test. The dried toxoid could be prepared in bulk and issued in bottles containing an exact number of units of toxoid; to this could be added a definite amount of a defined suspension of aluminium phosphate for the test.

Influence of Amount of Mineral Carrier on in-vivo Potency

When a sample of A.P.T. is to be tested for potency, the regulations of the Therapeutic Substances Act require that it be diluted to Lf 1 (one flocculating unit per c.cm.), and that two injections of 1 c.cm. each into normal guineapigs should be made four weeks apart. The guineapigs should be bled not later than three weeks after the second injection, and the sera assayed individually for their antitoxin values; from these the geometric mean is calculated.

The object of the test is to obtain a measure of the antigenicity of the prophylactic, the titre of which must be not less than Lf 50. To inject into guineapigs the same amounts of A.P.T. as are administered to a child would involve using excessive amounts owing to the difference in weight between test animal and child. A recent Government inquiry (see British Medical Journal, 194[illegible] [illegible] d that sam[illegible] which had been [illegible] SUMMARY [illegible] g high Schick-

Six cases of bilateral compression of the [illegible]ted in guinea- in the carpal tunnel are reported. All occur[illegible]ith a geometric mean value of at least two units of antit· per c.cm.

The dilution of the prophylactic reduces not only the toxoid content but also the mineral carrier, though it preserves their original proportions. Thus the amount of mineral carrier used in the test animal is never more than one twenty-fifth of that for human prophylaxis. Hitherto no animal experiments have been recorded on the potency of a diphtheria prophylactic which maintained the same concentration of carrier as in human prophylaxis and with a reasonably small quantity of toxoid.

It was observed that, when guineapigs were injected subcutaneously with 1 Lf doses of diluted A.P.T., nodules never developed, but they invariably appeared when a small dose (0·2 c.cm. or greater) of undiluted A.P.T. was used. Since the depot theory of Glenny et al. (1931), for the enhanced potency of A.P.T. over its parent formol toxoid, postulates a depot, or reservoir, of slowly liberated toxoid in the tissues, it follows that the diluted prophylactic should be antigenically inferior to the concentrated one.

It is therefore of practical importance, in human prophylaxis, to determine the optimal amount of carrier to use for both primary and secondary stimuli. With A.P.T. of varying mineral composition this is very difficult to ascertain. For example, it was found that A.P.T. derived from Mueller's (1939) *medium toxins* did not pass the animal potency test when prepared in the usual way, but did so easily with 1% sodium phosphate added to the formol toxoid used before the addition of alum. This produced a well-marked increase in the amount of precipitate per Lf.

The fact that a potent diphtheria prophylactic can be prepared simply by mixing purified toxoid with a suspension of aluminium phosphate facilitates the investigation of these important questions. By this means it is possible to determine quantitatively the influence of the amount of mineral carrier on the antitoxin response and to ascertain the optimal amount to be contained in diphtheria prophylactics of this type.

INVESTIGATION

For this investigation concentrated and purified toxoids and suspensions of pure aluminium phosphate were used; these were prepared as described above and were preserved with 1/10,000 sodium ethyl mercurithiosalicylate. Samples were made in which the ratio of toxoid to aluminium-phosphate carrier was varied. In all cases 1 Lf quantities of toxoid in 1 c.cm. amounts were injected into groups of at least 10 guineapigs. The dose was repeated four weeks later. A small quantity of blood (0·5 c.cm.) was collected from each animal at the end of the twenty-eight-day interval to obtain the average antitoxin titre four weeks after the first dose. Larger bleedings were made two weeks after the second dose, and each serum was individually assayed for its antitoxin content. From these results the geometric mean value was calculated for each group.

Results.—The results obtained are summarised in the table, with their statistical analysis, which reveals that in every case there was a chance of less than 1 in 100 of these being fortuitous. These results show that the amount of mineral carrier (aluminium phosphate) plays an important part in regulating the antigenic potency of such preparations. When a sample of diphtheria prophylactic is diluted to conform to the official method of assaying potency, the indicated efficiency of the prophylactic, measured by the numerical value of the antitoxin produced, is probably below that obtained from the undiluted preparation, owing to the reduction in the amount of mineral carrier used.

This is shown in series A (see table). The material used was composed initially of 3 mg./c.cm. of aluminium phosphate with a titre of Lf 50 and was diluted to Lf 1 for the test. The same sample of purified toxoid diluted to Lf 1 but mixed with 3 mg. of aluminium phosphate (corresponding to the preparation A as used for children with only its toxoid component reduced) would give (1) about ten times as much antitoxin for a primary stimulus (its value being taken as 2 units per c.cm. after one dose), and (2) about four times as much antitoxin with two doses (its value being taken as 8 units per c.cm. for two doses).

Particular importance should be attached to the very pronounced efficacy of the primary stimulus with preparations in which the amount of mineral carrier has been increased. Further, these results indicate that the optimal amount of mineral carrier required for maximal antitoxin production in guineapigs is approximately 2·75 mg. of aluminium phosphate for each injection.

INFLUENCE OF VARYING AMOUNT OF $AlPO_4$ ON POTENCY

(Antigen employed constant at 1 Lf per dose)

Series	$AlPO_4$ injected per dose (mg.)	Serum antitoxin titres u./ml.		Gain	Statistical analysis ‡						
		(I)*	(II)†	Ratio $\frac{II}{I}$	n	d.f.	Mean	Sd²	Sx²	s²	t
A	0·06	0·2	2·2	11·0	20	19	2·5	52·9	..	..	..
B	0·2	0·4	4·1	10·0	10	9	4·7	50·12	103 0	3·6	3 0
C	0·5	0·7	4·4	6 3	10	9	5·1	70·9	123·9	4·4	3·2
D	1·0	1·0	5·4	5·4	10	9	6·9	222·9	275·8	9·8	3·6
E	2·0	1·75	7·6	4·3	12	11	8·3	154·7	207·6	6·9	6·0
F	4·0	1·5	3·9	2·6	14	13	4·35	47·18	100·1	3·1	3·0

* 28 days after 1st dose (mean value).

† 14 days after 2nd dose (geometric mean).

‡ For this analysis the results from the 0·06 mg./ml. sample were compared with those from the others, using the formula :

$$t = \sqrt{\frac{\bar{x}}{s^2 \frac{(n_1+n_2)}{(n_1 . n_2)}}}.$$

It would be erroneous to assume that, because a child weighs at least thirty times as much as a guineapig, the best dose of mineral carrier to use in the diphtheria prophylactics for children should be thirty times the optimal amount for guineapigs.

For an accurate assessment of a sample of diphtheria prophylactic it would be more reasonable to use the same amount of carrier for both, but considerably less toxoid in the guineapigs. The figures in the table support this view, though the evidence is weakened by the high antitoxin levels which result from the need to conform to the official potency-test regulations, where 1 Lf of toxoid must be used. To obtain in the guineapig the level of circulating antitoxin which in the child is considered adequate for protection against diphtheria—i.e., about 1/50 unit per c.cm.—with the same amount of carrier, it is not unlikely that very much less than 1 unit of toxoid would be required, particularly when two doses are used.

The figures in the table also show that, as the amount of mineral carrier is increased, the "gain" resulting from the second inoculation is decreased. This aspect of the phenomenon of antitoxin production in the guineapig is being investigated and appears to be of considerable complexity.

The shape of the curve obtained when the "gain"—i.e., ratio of the second response to the primary—is plotted against the amount of aluminium phosphate injected suggested that it was a rectangular hyperbola. This was confirmed by the finding that the product of the "gain" and the number of mg. of aluminium phosphate plus 1 was a constant. The values obtained for each aluminium-phosphate level were :

$AlPO_4$ injected per dose (mg.)	*"Gain"*	*($AlPO_4$+1) × "gain"*
0·06	11·0	11·6
0·2	10·0	12·0
0·5	6·3	9·4
1·0	5·4	10·8
2·0	4·3	12·9
4·0	2·6	13·0

Here the constant is about 12.

Field trials with purified toxoid, aluminium-phosphate-precipitated, on several hundreds of children have been carried out by Dr. Guy Bousfield, who reports his findings separately.

DISCUSSION

It has been shown that it is possible to make a potent diphtheria prophylactic by first purifying the diphtheria toxoid and then incorporating it in a suspension of pure aluminium phosphate. Both the titre and the concentration of aluminium phosphate in the final product can be accurately regulated as required.

Though this new method permits of accurate reproduction from a chemical point of view, it does not necessarily follow that a similar degree of accuracy has been achieved in respect of physiological activity.

In some measure, however, this has been attained, as is shown by the fact that one of the most important variables—the amount of mineral carrier—can be controlled. Further, the removal of much foreign protein and other nitrogenous material initially present in the crude toxoid solutions must help to reduce variations.

From a strictly chemical point of view, if absolutely pure toxoid was used with the aluminium-phosphate carrier, there would appear to be no grounds for expecting variations in physiological activity in preparations of the same composition.

Data to hand have shown that the new prophylactic, when prepared as described, does yield products of unusually constant antigenicity ; but, before a complete report can be made on this point, more data are needed.

SUMMARY

A method is outlined for the preparation of a new diphtheria prophylactic, consisting of a purified toxoid precipitated by a suspension of a measured amount of pure aluminium phosphate.

The new prophylactic is antigenically potent, has good storage properties, and produces less reactions than does A.P.T. in sensitive persons.

A method is suggested for the production of a reference or standard diphtheria prophylactic.

In guineapigs the antitoxin response from the purified toxoid, aluminium-phosphate-precipitated, with a constant amount of toxoid is largely governed by the amount of mineral carrier it contains. This is particularly the case when the results of primary stimuli are examined.

For maximal antitoxin production in guineapigs the optimal amount of aluminium phosphate per dose is about 2·75 mg.

A simple mathematical equation has been found to express the relationship between the amount of aluminium phosphate injected and the ratio of the antitoxin obtained from two doses as against one of the same preparation.

My thanks are due to Dr. W. J. Martin, of the London School of Hygiene, for his expert advice on the statistical analysis. Important technical help was rendered me by W. C. Evans, PH.D.

CLINICAL TRIALS OF DIPHTHERIA TOXOID ALUMINIUM-PHOSPHATE-PRECIPITATED

TO DETERMINE OPTIMAL ALUMINIUM-PHOSPHATE CONTENT

GUY BOUSFIELD
M.D. Lond.

AT the request of Mr. L. B. Holt I tried to find out if there were any differences in immunity production when persons were inoculated with batches of the same parent diphtheria toxoid made up so that they contained various amounts of aluminium phosphate.

Holt's method of preparing the antigen renders it possible for the pure phosphate to be used, with great advantage, in that the amount of Al PO_4 added can be controlled at will. Using only the phosphate in his preparations, Holt had found that they were physiologically active as immunising agents in guineapigs. It thus became necessary to determine whether his findings could be confirmed in man.

It was essential to make observations only on subjects of reasonably comparable body-weight, who were without substantial basal immunity. The investigation was therefore limited to Schick-positive children between their first and second birthdays. A suburban area, where herd immunity was low, was selected for the work.

The possibility of reaching conclusions based on serum-antitoxin titrations was excluded by the age of the children: a study of the Schick-conversion rate was the only available method of comparing various samples of prophylactic. Nevertheless, I have repeatedly observed in the past that the Schick test will yield results which are generally comparable with those obtained by the more precise method of antitoxin titration, provided that the test is intelligently applied. Thus no apology is made for presenting this work based on the Schick standard.

IMMUNITY RESPONSES

As so often happens when unknown territory is being explored, a preliminary experiment had to be staged. It was necessary to determine what Lf dosage should be used so that it should neither be so large as to mask any differences between samples containing varying Al PO_4 concentrations, nor so small that the antigen content was insufficient to produce a reasonable Schick conversion rate.

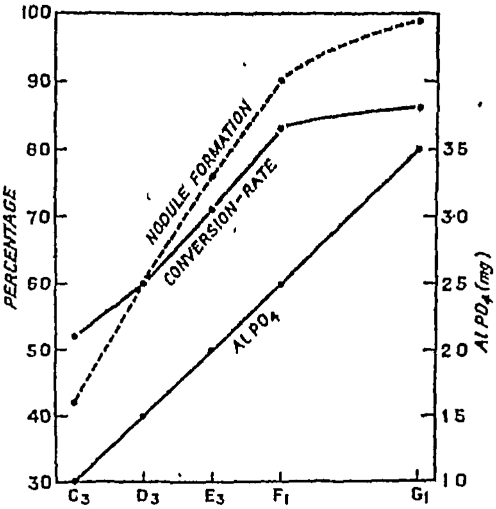

Fig. 1—Relation between amount of Al PO_4 injected, nodule formation, and Schick-conversion rate.

As a result of previous experiences with dilute antigens, the dosage adopted for the preliminary work was 0 3 c.cm. of a 10 Lf/c.cm. aluminium-phosphate toxoid, various samples supplied by Mr. Holt containing Al PO_4 in concentrations of 0·5, 1·0, 2·0, 3·0, and 4·0 mg. per c.cm. The actual quantities of Al PO_4 injected in the tests were thus three-tenths of the amounts described, as I was using the 0·3 c.cm. dose. Throughout the work described in this paper the injections were given subcutaneously, on the outer aspect of the upper arm, so that local reactions could be observed. Successive children were treated in rotation with the various samples of prophylactic, and post-Schick tests were performed twenty-eight days after the single injection of 0·3 c.cm. The batches yielded striking differences in the immunity response which they evoked; these are shown in table I. At this stage of the work it seemed possible that the findings in group E1 indicated that the optimum Al PO_4 dosage had been passed.

These results suggested the adoption of a larger Lf dosage and in consequence a slight corresponding increase in the total Al PO_4 injected. The next series thus received 0·5 c.cm. doses of 10 Lf/c.cm. preparations containing the same aluminium-phosphate concentrations as were used in the former investigation. The results appear in table II.

TABLE I—IMMUNITY RESPONSES IN 251 CHILDREN TO SINGLE INJECTIONS OF 0 3 C.CM. (3 LF UNITS OF TOXOID)

Group	Total Al PO_4 injected (mg.)	Schick results 28 days after injection		Conversion rate (%)
		Positive	Negative	
A1	0·15	41	5	*11*
B1	0·3	38	6	*13*
C1	0·6	35	15	*30*
D1	0·9	15	39	*72*
E1	1·2	19	39	*67*

When the investigation had gone this far it seemed that there was no reason to suppose that the findings in group E2 indicated that the optimal Al PO_4 concentration had yet been reached; so it was decided to extend the scope of the work without delay rather than to accumulate further evidence under the heading of table II. One thing that has to be appreciated in this kind of work is that no experiment can simply be extended to acquire further information. Each series must be complete in itself, so as to allow for minute differences in antigen composition, prevalence of traces of diphtheria infection in varying seasons, &c. These factors may explain the differences in conversion-rates which will be noted in table III, as compared with table II. Such variations render it impossible to present a composite table embodying all results. The trends of the curves are, however, sufficiently clear in the individual tables. For the above reasons I have always found it advisable *to provide for an overlap on the last experiment* when starting a new series.

Further samples of prophylactic had to be procured from Mr. Holt, and the Al PO_4 content of groups C2, D2, and E2 of table II were again used in the next stage of the investigation. The scope of this was extended by the inclusion of two further samples, F1 and G1, these containing 5 and 7 mg. of Al PO_4 per c.cm. respectively, the toxoid being maintained at 10 Lf/c.cm. These last five samples were prepared from a different parent toxoid. Table III shows the same upward trend in conversion-rates as the Al PO_4 dosage is increased.

The flattening of the curve when the 2·5 mg. dosage is reached is best shown in a graph, the rest of the rise being fairly steady. Fig. 1 illustrates the point and suggests that the optimum seems to be approached with the dose used in group G1. Clearly the work could not stop at this point, and a further sample of G1 strength, and two containing more Al PO_4, were prepared, H1 containing 10 mg. and I1 containing 15 mg. per c.cm. Results obtained with these three samples up to the time of publication are shown in table IV, which suggests that the optimal aluminium-phosphate dosage has been reached in sample H1 or thereabouts. At any rate, the

TABLE II—IMMUNITY RESPONSES IN 177 CHILDREN TO SINGLE INJECTIONS OF 0·5 C.CM. (5 LF UNITS OF TOXOID)

Group	Total Al PO_4 injected (mg.)	Schick results 28 days after injection		Conversion-rate (%)
		Positive	Negative	
A2	0·25	31	7	18
B2	0·5	26	11	30
C2	1·0	13	18	58
D2	1·5	10	28	74
E2	2·0	4	29	88

amount of the salt which can be added is governed by something more than theoretical considerations. Sample H1 contains about as much Al PO_4 as is convenient from the practical point of view, since prophylactics containing larger amounts leave copious white deposits wherever they fall and may, in vulgar parlance, be described as "messy."

Critics may say that this work is fragmentary. The answer is that one was exploring new territory and had to feel the way carefully so as not to produce unnecessarily severe local reactions as the Al PO_4 content of the prophylactics was increased. With the knowledge gained from the foregoing investigations it will be possible to stage one good experiment, and the next step will be to work out the range between 3 mg. and 15 mg. of Al PO_4 per c.cm. but allowing smaller differences between the various samples as regards their salt content. Thus the true curve and absolute theoretical optimum may be demonstrated in one large series. There is, however, no reason to delay publication of the present findings, which illustrate quite well the paramount importance of controlling carefully the amount of aluminium phosphate which must be added to the prophylactic if an optimal primary stimulus is required.

TABLE III—IMMUNITY RESPONSES IN 285 CHILDREN TO SINGLE INJECTIONS OF 0·5 C.CM. (5 LF UNITS OF TOXOID)

Group	Total Al PO_4 injected (mg.)	Schick results 28 days after injection		Conversion-rate (%)
		Positive	Negative	
C3	1·0	27	29	52
D3	1·5	22	33	60
E3	2·0	18	44	71
F1	2·5	9	45	83
G1	3·5	8	50	86

$\chi_4^2 = 22·7$. $P > 0·01$.

About half-way through the foregoing investigations the effect of increasing the aluminium salt on the immunity response was so pronounced that it was thought well to perform a small control experiment to meet possible criticism. Ten children therefore received a suspension of the Al PO_4 in 0·5 c.cm. doses of a 7·0 mg. per c.cm. preparation, but no antigen was included. On testing these ten children twenty-eight days later, all were as strongly Schick-positive as they had been originally.

NODULE FORMATION

The next endeavour was to determine to what extent nodule formation in the subcutaneous tissues was related to a satisfactory immunity response, and what bearing the Al PO_4 dosage had on the incidence and character of the nodules. Since all injections were deliberately given subcutaneously, it was easy to palpate for nodules at the time of the post-Schick test, twenty-eight days after the antigen had been administered. The findings are given in table V. They are so arranged that evidence in favour of the depot theory of stimulation appears in columns marked I and II, while arguments against it might be deduced from columns III and IV.

Taking the findings as a whole, columns I and II, favouring the depot theory, total 363 cases, while presumably contrary evidence in columns III and IV amounts to 144 cases. The evidence that satisfactory primary stimulation is bound up with some degree of local fibrosis and presumed depot action is thus about seven to three in favour of the depot theory.

In fig. 1, based on table III and on a portion of table V, it can readily be seen how striking is the resemblance between the conversion-rate curve and that of nodule formation and Al PO_4 content.

An interesting point arises in considering to what extent a true depot of any real permanency is likely to be established in the body after the injection of A.P.T. or similar prophylactics. It seems probable that the main deposit of antigen can only contribute to such a process for a relatively short time: encapsulation and occlusion from the circulatory or lymphatic systems must take place fairly rapidly, the enclosed prophylactic presumably serving no further useful purpose. So, if the depot theory is the true explanation of the success of A.P.T. and similar prophylactics, it seems probable that only that portion of precipitate near the periphery of the early inflammatory reaction is utilised, or is concerned with any sort of prolonged local depot action. That amount of A.P.T. must be very small, but I hold the view that the actual Lf dosage necessary to provide a stimulus is probably extremely small. We have to use relatively large doses to create those conditions which render it possible for a small proportion of the injection to be utilised optimally by the body.

TABLE IV—IMMUNITY RESPONSES IN 134 CHILDREN TO SINGLE INJECTIONS OF 0·5 C.CM. (5 LF UNITS OF TOXOID)

Group	Total Al PO_4 injected (mg.)	Schick results 28 days after injection		Conversion rate (%)
		Positive	Negative	
G2	3·5	7	35	83
H1	5·0	3	42	93
I1	7·5	4	43	91

Whatever the explanation is, the fact emerges clearly from the foregoing observations that the characteristic of nodule formation is most closely bound up with the use of an antigen with a reasonably high Al PO_4 content; and that the Schick-conversion rate improves with the incidence of a high percentage of nodules obtained as a result of using increasing quantities of aluminium phosphate. Generally speaking, as more Al PO_4 was

ATELECTASIS AFTER PARTIAL GASTRECTOMY

P. STRINGER
M.B. Lond., F.R.C.S.
LATE SURGICAL REGISTRAR, CHARING CROSS HOSPITAL, LONDON

ATELECTASIS, or collapse, has been recognised as probably the commonest postoperative chest complication. Most writers consider that bronchial occlusion, due to inspiration of a mucous plug or resulting from inflammatory œdema of the lining epithelium, is the usual cause; but there is little reference in the literature to the time of onset of postoperative atelectasis.

Thomas (1938) pointed out that, though bronchial occlusion was probably the mechanical factor responsible, collapse did not supervene immediately, citing Brooks's (1938) use of a balloon to produce temporary occlusion of the bronchial lumen as a form of collapse therapy in pulmonary tuberculosis. Collapse did not take place usually until 4–6 hours after inflation of the balloon. Consideration of the time-incidence of occlusion is obviously of importance in the use of bronchial aspiration. Haight (1938) showed the value of such treatment in the early stages of atelectasis to prevent its further development.

It was therefore decided to radiograph the chests of patients who had undergone partial gastrectomy at Charing Cross Hospital and Ashridge E.M.S. Hospital *to determine with more accuracy the time of onset of atelectasis.* Radiography was done immediately after, four hours after, and twenty-four hours after operation. In certain cases, in which the previous radiological findings and the clinical condition indicated, radiography was done later also. Radiological interpretation was not always easy, and an additional handicap was that the first film was taken with the patient supine, the later ones with the patient erect. During the investigation the frequency of atelectasis and certain possible causal factors, such as age and a previous history of chest disease, were also considered.

TABLE I—AGE-INCIDENCE OF ABNORMAL POSTOPERATIVE RADIOLOGICAL SIGNS

Age-group (years)	Number of cases			
	With radiological signs		Without radiological signs	
	Males	Females	Males	Females
Under 30 ..	..	1	..	..
30–40 ..	7	2	11	2
40–50 ..	8	..	12	1
50–60 ..	5	1	3	..
60 and over ..	2	..	..	..

The preoperative preparation was standard in almost all cases. The patient received sulphathiazole gr. 2 to start and then gr. 1 four-hourly. Breathing exercises, starting on the day before operation, were a routine. The immediate preoperative medication was 'Omnopon' gr. $^1/_3$, scopolamine gr. $^1/_{150}$ half an hour before operation. The patients numbered 55 (48 males and 7 females), and 26 of them (22 males and 4 females) developed postoperatively abnormal radiological signs including those of various stages of atelectasis and increased hilar striation or vascular markings of a lobe, which may precede atelectasis.

Table I shows that the preponderance of patients operated on fell into the groups 30–40 years and 40–50. Similarly, the highest incidence of those with radiological signs fell into these particular groups. No particular age-group appears especially liable to show such signs, though a higher incidence is to be noted among the older ones, as would be expected.

Previous respiratory infection has long been recognised as predisposing to postoperative atelectasis. The chronic bronchitic, or the patient with slight bronchiectasis producing a little mucopurulent sputum every morning, is especially liable.

Table II shows that the great majority of the patients gave no history of previous chest disease. Almost the same number of patients with chronic bronchitis and emphysema showed radiological signs after operation as those which did not, although not in all cases was the diagnosis of chronic bronchitis and emphysema confirmed radiologically. From this small series, therefore, it does not appear that previous chest disease necessarily predisposes to postoperative atelectasis.

Anæsthesia.—Much of the recent literature on the subject of postoperative chest complications has considered the influence of forms of anæsthesia on their causation. Such a comparison is hardly possible in the present series, since the anæsthesia in practically all cases was the same. High spinal anæsthesia with light 'Nupercaine' 1 in 1500 or 1 in 1000 by Lake's modification of Howard Jones's method was used almost exclusively. Of the patients who showed radiological evidence of chest complications, 3 received supplementary gas and oxygen; in 4 cases anæsthesia other than spinal was used, 3 of them receiving gas-oxygen and cyclopropane, and the other regional and splanchnic block. Only 3 patients received general anæsthesia alone; all showed abnormal postoperative radiological signs.

TABLE II—RELATION OF ABNORMAL POSTOPERATIVE RADIOLOGICAL SIGNS TO HISTORY OF CHEST DISEASE

Previous condition of chest	Number of cases	
	With radiological signs	Without radiological signs
No previous chest disease	18	21
Chronic bronchitis and emphysema	6	5
Previous chest disease	1 (old pleural effusion) 1 (bronchopneumonia)	2 (bronchopneumonia) 1 (rheumatic carditis)

Time of Operation.—Brock (1936) has emphasised that in the drier seasons a higher incidence of collapse might be expected owing to greater fluid loss from sweating, with consequent increased viscidity of sputum and possible retention in the terminal bronchioles. The seasonal incidence of radiological complications was therefore noted.

Table III shows that the cases with radiological evidence of pulmonary complication occurred far more frequently in the period March 31–Oct. 1. This suggests that the time of year, possibly for the reasons already suggested, may contribute to the incidence of postoperative chest complications; but many other factors, such as the temperature on the day of operation and the humidity of operating-theatre and wards, would also have to be considered.

TABLE III—SEASONAL INCIDENCE OF ABNORMAL POSTOPERATIVE RADIOLOGICAL SIGNS

Time of year	Number of cases	
	With radiological signs	Without radiological signs
Oct. 31–March 1 ..	8	17
March 31–Oct. 1 ..	18	12

POSTOPERATIVE CHEST COMPLICATIONS

Collapse.—This includes patchy or lobular atelectasis, partial collapse (atelectasis affecting part of a lobe), and total or massive collapse (collapse of one or more lobes). The first postoperative film was taken on the operating-table immediately after operation, and in all those cases which later showed abnormal radiological signs none were noted in this film (see table IV). The first signs were noted in the film taken four hours after operation. Altogether there were 13 cases of collapse, of which 5 were first manifest in the four-hour film, showing patchy atelectasis

TABLE IV—TIME OF ONSET OF POSTOPERATIVE ATELECTASIS

Time of radiography after operation	Number of cases of atelectasis
Immediate	None
4 hours	5
24 hours	6
Later	2
Total ..	13

In the film taken at twenty-four hours 11 cases were confirmed radiologically. The 5 cases noted in the four-hour film all showed development of the original patchy atelectasis, and in some a definite partial collapse of a lobe was evident. The other 6 showed signs of commencing patchy atelectasis. In 2 of the 11 cases observed in the film taken at twenty-four hours atelectasis affected both bases; in 5 it affected the right side alone, and in 4 cases the left side alone. In the 2 other cases in the series radiological evidence of collapse was not manifest until three and five days after operation (see table IV). Usually the lung fields on the affected side began to clear four or five days after operation, although in 4 cases the other side showed signs of atelectasis before this event.

In all cases of collapse there were clinical signs and symptoms, though, as Gius (1940) says, "the physical signs in the early stages are notoriously inconstant and variable. Transient physical signs are found in the chest after nearly all upper abdominal operations, and a diagnosis of atelectasis is normally not warranted on the basis of physical signs alone." The temperature rose to 100–101° F; the pulse-rate correspondingly to 100–120. A patchy distribution of râles and high-pitched rhonchi developed in some cases, and occasionally areas of bronchial breathing with increased vocal resonance and diminished percussion note. Gross mediastinal shift was not observed in any case. Sputum, at first scanty, tenacious, and viscid, became more copious and mucopurulent in a few cases. In the 2 cases occurring rather later than the others the associated rise of temperature and pulse-rate without other obvious cause suggested atelectasis, which was confirmed by radiography.

Appearances Resembling Collapse.—In 10 of the 26 cases increase in the vascular markings either in the lower lobes or hilar regions was noted radiologically. None were noted in the immediate postoperative film, 7 appeared in the four-hour film, and others at twenty-four hours. Some noted in the four-hour film had cleared at twenty-four hours. Mention is made of these because, where atelectasis was first noted radiologically at twenty-four hours, increase in the vascular markings of the affected areas was noted in the four-hour film (see below).

Other Types.—In 3 cases pulmonary complications other than collapse occurred. In 1 of them increased density in the right hilar region was noted radiologically at twenty-four hours. Three days later the patient developed bronchopneumonia. The second case showed the clinical picture of bronchitis, developing nearly a week after operation. Radiography revealed increased markings in the left hilar region. In the third case no abnormal signs were noted in the usual postoperative films, but five days later the patient developed signs and symptoms of collapse at his right base. The film then taken showed collapse of right lower lobe, with a small pleural effusion.

In another case (not included in the series) the patient developed bronchopneumonia secondary to a subphrenic abscess. Eventually death took place from toxæmia and paralytic ileus. This was the only death from a chest or other complication and was secondary to a subphrenic abscess. No radiological signs were visible until the fifth day, when they consisted of raising of the left diaphragm, with distension of the splenic flexure, and partial collapse. Bronchopneumonic changes supervened later.

TIME OF RADIOLOGICAL APPEARANCE OF ATELECTASIS

Signs of commencing patchy atelectasis were seen in the four-hour film in 5 cases (table IV), none being noted in the immediate postoperative films. Four hours after operation clinical features are of little value in the diagnosis of postoperative atelectasis, as already emphasised. At this stage, therefore, only radiography can establish the diagnosis. In the films taken at this time, however, 7 cases were reported as having increased vascular markings of the hilar region or lower lobes. This appearance is not easy to distinguish from atelectasis. In some cases the signs of patchy atelectasis developed in the film taken at twenty-four hours. In the others at twenty-four hours the radiological signs were similar to those of the four-hour film or had disappeared. In no case in which hyperæmia alone was noted in the film at twenty-four hours did atelectasis develop subsequently. The cases of atelectasis observed in the four-hour film, however, were all more marked at twenty-four hours. At that stage 6 more cases had developed—i.e., by twenty-four hours 11 out of the 13 cases had shown themselves radiologically. Neither of the 2 cases arising subsequent to this time showed signs of hyperæmia or atelectasis in the postoperative film. It was the clinical condition that suggested the development of atelectasis, which was confirmed by radiography.

Thus, in the observation and diagnosis of postoperative atelectasis, it seems that radiography twenty-four hours after operation is most valuable. Collapse previously noted in the four-hour film will be definitely confirmed, and most of the cases of collapse will have appeared by then (11 out of 13 in this series). Further, the changes, interpreted as increased vascular markings of hilar or basal regions, have either regressed or have developed into early patchy atelectasis by this time. Twenty-four hours after operation the clinical signs and symptoms of collapse are slight and often misleading. Radiography alone can establish the diagnosis.

It is therefore suggested that, to show whether or not atelectasis has occurred, a routine film should be taken twenty-four hours after operation. If the hypothesis is accepted that bronchial occlusion by a mucous plug is the chief ætiological factor, and that early bronchial aspiration is the correct treatment, its use at this stage is indicated if a film taken at this time shows atelectasis. Immediate postoperative bronchoscopy, in cases where spinal anæsthesia has been used, necessitates local anæsthesia of the pharynx, larynx, and trachea; but bronchoscopy may be performed under local anæsthesia twenty-four hours after operation, and the difficulties associated with its use immediately after operation would not then arise.

SUMMARY

The incidence of atelectasis after partial gastrectomy has been investigated by radiography of the chest immediately after, four hours after, and twenty-four hours after operation.

Of 55 cases investigated 26 showed abnormal post-operative radiological signs, and out of these 26 cases 13 showed signs of lobular, partial, or total atelectasis.

No signs were noted in the immediate postoperative film; signs first appeared radiologically at four hours in

5 cases, and at twenty-four hours in a further 6 cases. The other 2 cases of atelectasis did not develop until later.

Besides signs of atelectasis there were increased vascular markings in some cases, and 3 other cases showed bronchopneumonia, bronchitis, and collapse with effusion.

The findings suggest that the film taken twenty-four hours after operation is the most valuable in determining whether or not atelectasis has occurred.

If the cause of atelectasis is bronchial occlusion by a mucous plug, bronchoscopy should then be considered.

I should like to thank Mr. Norman Lake, at whose suggestion this investigation was carried out, for his continued advice and encouragement in the preparation of this article.

PAIN AND THE HEALING OF PEPTIC ULCERS

A. Morton Gill
M.D. Lond., F.R.C.P.
ASSISTANT PHYSICIAN, WEST LONDON HOSPITAL

It has been known for many years that at a certain stage peptic ulcers may be present without associated symptoms, of which the chief is pain.

This curious feature is seen in all grades of peptic ulcer, from the acute to the very chronic. Most clinicians can remember patients who suddenly had violent, profuse, and dangerous hæmatemesis, without any prodromal dyspepsia, and in some of whom gastroscopy, performed within a few days of the hæmorrhage, revealed an acute ulcer healing rapidly and spontaneously, without pain at any time. At the other extreme is the callous ulcer, of which the following is an example:

A man, aged 82, had severe epigastric pain, loss of appetite, and rapid emaciation. A barium meal showed a huge ulcer involving most of the lesser curve of the pars media. Its size alone suggested malignancy, yet within forty-eight hours of being put to bed on hourly milk feeds the patient lost his pains. Within a fortnight his appetite had returned, and within a month the ulcer crater had diminished to half its former size. Nevertheless, the crater never disappeared, and at the patient's death, of arteriosclerotic cardiovascular disease two years later, it was still present, though there had never been any recurrence of pain or indigestion.

On the other hand, the ulcer may heal and the pain continue, as it does in a phantom limb.

A woman, aged 42, had a small stubborn gastric ulcer, for which she was fed on milk by continuous intragastric drip for six weeks. At the end of this time, as her pains were no better, it was decided to perform a partial gastrectomy. The surgeon asked that she should be gastroscoped first, and at gastroscopy the ulcer was found to be completely healed, a small depressed epithelised scar being seen. Some students, present at the examination, were shown the puckered folds produced by the healing of the ulcer. The patient, overhearing this demonstration, realised that at last her ulcer had gone, and from that moment she lost her pain.

Not so fortunate was a woman, aged 38, whose duodenal ulcer was treated by continuous milk drip and whose pain remained unrelieved. As a result a partial gastrectomy was advised; but, owing to some mischance, a barium meal was not given before operation. At laparotomy no ulceration was present, a small scar only being found in the duodenum.

It seems therefore clear that one of the main clinical criteria of ulcer activity—i.e., pain—is unreliable, since ulcers can be present for a long time without producing any discomfort; and, on the other hand, though an ulcer may be healed, the patient may continue to feel the pain usually associated with an active ulcer.

HEALING FACTORS

The factors that cause an ulcer to heal are no easier to understand.

A man, aged 50, was given a long rest in bed, with careful diet, for his gastric ulcer; and, though he soon lost all his pain and felt very well, the ulcer, viewed at intervals through the gastroscope, showed no signs of healing.

The patient accepted the decision to operate, and a week later, the day before that fixed for the operation, a final gastroscopy was performed. The ulcer was healing rapidly, operation was postponed, and in another week no crater could be seen, a white scar marking the site of a hitherto peculiarly intractable lesion.

Of the various measures used to encourage ulcers to heal, some authorities emphasise the value of rest in bed, others forbid tobacco, others pay strict attention to diet, others favour various antacids, acid neutralisers, acid buffers, acid inhibitors. It is perhaps heresy to doubt whether any of these are necessary; yet the following experience is suggestive:

A consecutive series of 20 patients, each with a chronic gastric ulcer, were given a daily hypodermic injection of 1 c.cm. of distilled water. They were ambulant, their diet was unrestricted and even disregarded, they were given no medicines, and those who enjoyed smoking were encouraged to continue.

With one exception all lost their pains as quickly—i.e., within a few days—as a control series treated along orthodox lines. Healing of the ulcers was observed gastroscopically and took place in the usual time—i.e., in 4–8 weeks from the start of treatment.

The exception was a man who was worried about his wife's illness. His pain continued, and his ulcer showed no sign of healing. After his third gastroscopy, some four weeks from the beginning of treatment, he was told that his ulcer had almost healed. Thereupon his pain went, within a fortnight his ulcer really was healing, and within a month it was completely healed.

DISCUSSION

No doubt in a larger series there would have been some failures, and no-one would wish to use distilled-water injections as routine ulcer therapy. Nevertheless, the fact remains that ulcers may heal after a series of injections of a completely inert fluid such as distilled water.

Hubacher [1] records favourable results following the injection of extracts of stomach and small intestine; and Morrison [2] has obtained equally good results by the oral administration of normal gastric juice.

It is clear that any one of several different treatments, having apparently nothing in common, may be associated with the healing of peptic ulcers. From this it seems fair to argue that the essential factor is the patient's belief that his treatment is going to be successful. Whether he agrees or not with the treatment matters not at all in the case of a man with pernicious anæmia—a few injections of liver extract, and he is well. Not so the man with a gastric ulcer—not only must he be satisfied that his treatment is proceeding along the correct lines, but also he must find himself in a sympathetic environment and be protected from protracted anxieties.

Ulcers are not healed by diet alone, nor by injections, nor by medicines, but because the man with the ulcer comes under the care of a physician who is able to transmit some of his own confidence to his patient. Because it is common sense to rest a diseased organ and to give rest to a man suffering from disease, so we continue to treat ulcers by advising rest, a dietetic holiday, and a temporary escape from the worry and strain of the daily round. If the habits of these patients could be altered permanently, they might have no relapses.

and total or massive collapse (collapse of one or more lobes). The first postoperative film was taken on the operating-table immediately after operation, and in all those cases which later showed abnormal radiological signs none were noted in this film (see table IV). The first signs were noted in the film taken four hours after operation. Altogether there were 13 cases of collapse, of which 5 were first manifest in the four-hour film, showing patchy atelectasis

TABLE IV—TIME OF ONSET OF POSTOPERATIVE ATELECTASIS

Time of radiography after operation	Number of cases of atelectasis
Immediate	None
4 hours	5
24 hours	6
Later	2
Total ..	13

In the film taken at twenty-four hours 11 cases were confirmed radiologically. The 5 cases noted in the four-hour film all showed development of the original patchy atelectasis, and in some a definite partial collapse of a lobe was evident. The other 6 showed signs of commencing patchy atelectasis. In 2 of the 11 cases observed in the film taken at twenty-four hours atelectasis affected both bases; in 5 it affected the right side alone, and in 4 cases the left side alone. In the 2 other cases in the series radiological evidence of collapse was not manifest until three and five days after operation (see table IV). Usually the lung fields on the affected side began to clear four or five days after operation, although in 4 cases the other side showed signs of atelectasis before this event.

In all cases of collapse there were clinical signs and symptoms, though, as Gius (1940) says, " the physical signs in the early stages are notoriously inconstant and variable. Transient physical signs are found in the chest after nearly all upper abdominal operations, and a diagnosis of atelectasis is normally not warranted on the basis of physical signs alone." The temperature rose to 100–101° F; the pulse-rate correspondingly to 100–120. A patchy distribution of râles and high-pitched rhonchi developed in some cases, and occasionally areas of bronchial breathing with increased vocal resonance and diminished percussion note. Gross mediastinal shift was not observed in any case. Sputum, at first scanty, tenacious, and viscid, became more copious and mucopurulent in a few cases. In the 2 cases occurring rather later than the others the associated rise of temperature and pulse-rate without other obvious cause suggested atelectasis, which was confirmed by radiography.

Appearances Resembling Collapse.—In 10 of the 26 cases increase in the vascular markings either in the lower lobes or hilar regions was noted radiologically. None were noted in the immediate postoperative film, 7 appeared in the four-hour film, and others at twenty-four hours. Some noted in the four-hour film had cleared at twenty-four hours. Mention is made of these because, where atelectasis was first noted radiologically at twenty-four hours, increase in the vascular markings of the affected areas was noted in the four-hour film (see below).

Other Types.—In 3 cases pulmonary complications other than collapse occurred. In 1 of them increased density in the right hilar region was noted radiologically at twenty-four hours. Three days later the patient developed bronchopneumonia. The second case showed the clinical picture of bronchitis, developing nearly a week after operation. Radiography revealed increased markings in the left hilar region. In the third case no abnormal signs were noted in the usual postoperative films, but five days later the patient developed signs and symptoms of collapse at his right base. The film then taken showed collapse of right lower lobe, with a small pleural effusion.

In another case (not included in the series) the patient developed bronchopneumonia secondary to a subphrenic abscess. Eventually death took place from toxæmia and paralytic ileus. This was the only death from a chest or other complication and was secondary to a subphrenic abscess. No radiological signs were visible until the fifth day, when they consisted of raising of the left diaphragm, with distension of the splenic flexure, and partial collapse. Bronchopneumonic changes supervened later.

TIME OF RADIOLOGICAL APPEARANCE OF ATELECTASIS

Signs of commencing patchy atelectasis were seen in the four-hour film in 5 cases (table IV), none being noted in the immediate postoperative films. Four hours after operation clinical features are of little value in the diagnosis of postoperative atelectasis, as already emphasised. At this stage, therefore, only radiography can establish the diagnosis. In the films taken at this time, however, 7 cases were reported as having increased vascular markings of the hilar region or lower lobes. This appearance is not easy to distinguish from atelectasis. In some cases the signs of patchy atelectasis developed in the film taken at twenty-four hours. In the others at twenty-four hours the radiological signs were similar to those of the four-hour film or had disappeared. In no case in which hyperæmia alone was noted in the film at twenty-four hours did atelectasis develop subsequently. The cases of atelectasis observed in the four-hour film, however, were all more marked at twenty-four hours. At that stage 6 more cases had developed—i.e., by twenty-four hours 11 out of the 13 cases had shown themselves radiologically. Neither of the 2 cases arising subsequent to this time showed signs of hyperæmia or atelectasis in the postoperative film. It was the clinical condition that suggested the development of atelectasis, which was confirmed by radiography.

Thus, in the observation and diagnosis of postoperative atelectasis, it seems that radiography twenty-four hours after operation is most valuable. Collapse previously noted in the four-hour film will be definitely confirmed, and most of the cases of collapse will have appeared by then (11 out of 13 in this series). Further, the changes, interpreted as increased vascular markings of hilar or basal regions, have either regressed or have developed into early patchy atelectasis by this time. Twenty-four hours after operation the clinical signs and symptoms of collapse are slight and often misleading. Radiography alone can establish the diagnosis.

It is therefore suggested that, to show whether or not atelectasis has occurred, a routine film should be taken *twenty-four hours after operation.* If the hypothesis is accepted that bronchial occlusion by a mucous plug is the chief ætiological factor, and that early bronchial aspiration is the correct treatment, its use at this stage is indicated if a film taken at this time shows atelectasis. Immediate postoperative bronchoscopy, in cases where spinal anæsthesia has been used, necessitates local anæsthesia of the pharynx, larynx, and trachea; but bronchoscopy may be performed under local anæsthesia twenty-four hours after operation, and the difficulties associated with its use immediately after operation would not then arise.

SUMMARY

The incidence of atelectasis after partial gastrectomy has been investigated by radiography of the chest immediately after, four hours after, and twenty-four hours after operation.

Of 55 cases investigated 26 showed abnormal postoperative radiological signs, and out of these 26 cases 13 showed signs of lobular, partial, or total atelectasis.

No signs were noted in the immediate postoperative film; signs first appeared radiologically at four hours in

5 cases, and at twenty-four hours in a further 6 cases. The other 2 cases of atelectasis did not develop until later.

Besides signs of atelectasis there were increased vascular markings in some cases, and 3 other cases showed bronchopneumonia, bronchitis, and collapse with effusion.

The findings suggest that the film taken twenty-four hours after operation is the most valuable in determining whether or not atelectasis has occurred.

If the cause of atelectasis is bronchial occlusion by a mucous plug, bronchoscopy should then be considered.

I should like to thank Mr. Norman Lake, at whose suggestion this investigation was carried out, for his continued advice and encouragement in the preparation of this article.

PAIN AND THE HEALING OF PEPTIC ULCERS

A. MORTON GILL
M.D. Lond., F.R.C.P.
ASSISTANT PHYSICIAN, WEST LONDON HOSPITAL

IT has been known for many years that at a certain stage peptic ulcers may be present without associated symptoms, of which the chief is pain.

This curious feature is seen in all grades of peptic ulcer, from the acute to the very chronic. Most clinicians can remember patients who suddenly had violent, profuse, and dangerous hæmatemesis, without any prodromal dyspepsia, and in some of whom gastroscopy, performed within a few days of the hæmorrhage, revealed an acute ulcer healing rapidly and spontaneously, without pain at any time. At the other extreme is the callous ulcer, of which the following is an example:

> A man, aged 82, had severe epigastric pain, loss of appetite, and rapid emaciation. A barium meal showed a huge ulcer involving most of the lesser curve of the pars media. Its size alone suggested malignancy, yet within forty-eight hours of being put to bed on hourly milk feeds the patient lost his pains. Within a fortnight his appetite had returned, and within a month the ulcer crater had diminished to half its former size. Nevertheless, the crater never disappeared, and at the patient's death, of arteriosclerotic cardiovascular disease two years later, it was still present, though there had never been any recurrence of pain or indigestion.

On the other hand, the ulcer may heal and the pain continue, as it does in a phantom limb.

> A woman, aged 42, had a small stubborn gastric ulcer, for which she was fed on milk by continuous intragastric drip for six weeks. At the end of this time, as her pains were no better, it was decided to perform a partial gastrectomy. The surgeon asked that she should be gastroscoped first, and at gastroscopy the ulcer was found to be completely healed, a small depressed epithelised scar being seen. Some students, present at the examination, were shown the puckered folds produced by the healing of the ulcer. The patient, overhearing this demonstration, realised that at last her ulcer had gone, and from that moment she lost her pain.

Not so fortunate was a woman, aged 38, whose duodenal ulcer was treated by continuous milk drip and whose pain remained unrelieved. As a result a partial gastrectomy was advised; but, owing to some mischance, a barium meal was not given before operation. At laparotomy no ulceration was present, a small scar only being found in the duodenum.

It seems therefore clear that one of the main clinical criteria of ulcer activity—i.e., pain—is unreliable, since ulcers can be present for a long time without producing any discomfort; and, on the other hand, though an ulcer may be healed, the patient may continue to feel the pain usually associated with an active ulcer.

HEALING FACTORS

The factors that cause an ulcer to heal are no easier to understand.

> A man, aged 50, was given a long rest in bed, with careful diet, for his gastric ulcer; and, though he soon lost all his pain and felt very well, the ulcer, viewed at intervals through the gastroscope, showed no signs of healing.
>
> The patient accepted the decision to operate, and a week later, the day before that fixed for the operation, a final gastroscopy was performed. The ulcer was healing rapidly, operation was postponed, and in another week no crater could be seen, a white scar marking the site of a hitherto peculiarly intractable lesion.

Of the various measures used to encourage ulcers to heal, some authorities emphasise the value of rest in bed, others forbid tobacco, others pay strict attention to diet, others favour various antacids, acid neutralisers, acid buffers, acid inhibitors. It is perhaps heresy to doubt whether any of these are necessary; yet the following experience is suggestive:

> A consecutive series of 20 patients, each with a chronic gastric ulcer, were given a daily hypodermic injection of 1 c.cm. of distilled water. They were ambulant, their diet was unrestricted and even disregarded, they were given no medicines, and those who enjoyed smoking were encouraged to continue.
>
> With one exception all lost their pains as quickly—i.e., within a few days—as a control series treated along orthodox lines. Healing of the ulcers was observed gastroscopically and took place in the usual time—i.e., in 4–8 weeks from the start of treatment.
>
> The exception was a man who was worried about his wife's illness. His pain continued, and his ulcer showed no sign of healing. After his third gastroscopy, some four weeks from the beginning of treatment, he was told that his ulcer had almost healed. Thereupon his pain went, within a fortnight his ulcer really was healing, and within a month it was completely healed.

DISCUSSION

No doubt in a larger series there would have been some failures, and no-one would wish to use distilled-water injections as routine ulcer therapy. Nevertheless, the fact remains that ulcers may heal after a series of injections of a completely inert fluid such as distilled water.

Hubacher[1] records favourable results following the injection of extracts of stomach and small intestine; and Morrison[2] has obtained equally good results by the oral administration of normal gastric juice.

It is clear that any one of several different treatments, having apparently nothing in common, may be associated with the healing of peptic ulcers. From this it seems fair to argue that the essential factor is the patient's belief that his treatment is going to be successful. Whether he agrees or not with the treatment matters not at all in the case of a man with pernicious anæmia—a few injections of liver extract and he is well. Not so the man with a gastric ulcer—not only must he be satisfied that his treatment is proceeding along the correct lines, but also he must find himself in a sympathetic environment and be protected from protracted anxieties.

Ulcers are not healed by diet alone, nor by injections, nor by medicines, but because the man with the ulcer comes under the care of a physician who is able to transmit some of his own confidence to his patient. Because it is common sense to rest a diseased organ and to give rest to a man suffering from disease, so we continue to treat ulcers by advising rest, a dietetic holiday, and a temporary escape from the worry and strain of the daily round. If the habits of these patients could be altered permanently, they might have no relapses.

Reviews of Books

A GUIDE TO THE TUBERCULOUS (2nd ed., London: William Heinemann Medical Books, pp. 120, 3*s.* 6*d.*) is so far the only textbook on tuberculosis written primarily for the patient, and it is hard to see how it could be bettered. Dr. G. S. Erwin, medical superintendent of the Liverpool Sanatorium at Frodsham, answers all the patient's questions in simple terms, dispelling the terrors of the unknown, and reassuring without false optimism. The second edition smooths out many of the roughnesses of the first. Short sections on interdependent psychoneurotic conditions, and the effects of air travel on artificial pneumothorax, have been added, together with some interesting social statistics.

In A PRELUDE TO MODERN SCIENCE (London: Cambridge University Press, 50*s.*) Prof. Charles Singer and Mr. C. Rabin discuss the history, sources, and circumstances of the *Tabulæ Anatomicæ Sex* of Vesalius, has just been published by the Wellcome Historical Medical Museum. Students of medical history will welcome this careful study and the beautiful plates and figures which illustrate it.

Sir John Conybeare's MEDICINE (Edinburgh: E. & S. Livingstone, pp. 1170, 30*s.*) has reached its 8th edition. A section on the uses of penicillin has been added, and the articles on malaria, blackwater fever, bacillary dysentery, and typhus have been rewritten. An article on the menopause has been added, and the articles on thyrotoxicosis and diseases of the pituitary have been brought up to date. An appendix on aviation considers physiological problems arising at great altitudes and high speeds. Tables of physiological normals, just inside the cover, will be welcome to all.

T. F. Rhodes's guide to the chemistry of crime detection (FORENSIC CHEMISTRY, London: Chapman and Hall, pp. 164, 15*s.*) reflects his experience in the laboratories of the Department of Technical Police at Lyons, the famous Locard school. It is hard-pared technical reading, largely the collected writings of contemporary experts in this field, but embellished with a first-class monograph on the chemistry of questioned documents. The rest of the text is a quaint mixture of tradition in forensic chemistry—a fifth of the references are over 40 years old—and of shrewd practical evaluation of technical detail which betrays the laboratory expert. The section on blood and other stains is poor and outdated in comparison with the substance of the book.

The PROCEEDINGS OF THE CONFERENCE ON DIAGNOSIS IN STERILITY, 1945, are edited by Earl T. Engle, PH.D. (Springfield, Ill.: C. C. Thomas, pp. 237, $5). The conference was called in New York by the National Committee on Maternal Health, and the report will interest those already possessing some special knowledge of problems of human fertility and infertility. Most of the speakers had original contributions to make and plenty of clinical material to quote from. The most disappointing sections are those on the laboratory examination of seminal specimens and the post-coital examination of cervical mucus. Those on testicular and endometrial biopsy, the accessory glands, basal temperature charts, history-taking, tubal patency, and pelvic congestion throw some fresh light, and Dr. Kenyon's working hypothesis of the mechanism of sterility is a nice piece of speculation on the possibly depressive action of androgens on the seminiferous epithelium.

In a useful little manual (PRINCIPLES OF THE CONTACT LENS, London: H. Kimpton, pp. 88, 10*s.* 6*d.*) Mr. H. Treissman, F.R.C.S., describes the development and optical properties of contact lenses, and their advantages over ordinary spectacles. Many of the indications for their use given here have not yet been put to the test, and on the whole the advice is a little over-enthusiastic. Before these lenses can be tolerated there must be a very strong incentive, or the arduous preliminaries will discourage the prospective wearer. Vanity alone is not a sufficient incentive. For patients with keratoconus or mustard-gas keratitis, however, they give visual improvement which can be obtained by no other means, and their manufacture would be amply justified on these grounds alone. The Dallos moulded lens is the chief type described, and little is said of the more recently developed plastic contact lenses, which can be more easily manufactured at a smaller cost. Plastic lenses may in time largely replace the glass variety.

The pages on PENICILLIN IN THE TREATMENT OF INFECTIONS have now been reprinted from the *Oxford Loose-Leaf Medicine* as a conveniently slim book, which may be obtained from the Oxford University Press for 8*s.* 6*d.*

The 5th edition of Dr. R. W. Fairbrother's TEXTBOOK OF BACTERIOLOGY (London: Heinemann, pp. 480, 17*s.* 6*d.*) has been thoroughly revised, and advances in the subject since the 1937 edition have been added. The medical student will find here all that he needs for examinations, and more.

The 1946 YEAR BOOK OF GENERAL MEDICINE (Chicago: Year Book Publishers, pp. 772: 21*s.*) carries the usual stimulating quiz on the cover. It contains sections on infectious diseases, diseases of the chest, the blood and blood-forming organs, the heart and blood-vessels, the digestive system, and metabolism. It can be obtained in London from Messrs. H. K. Lewis & Co.

The fifth edition of Prof. Arthur Hale Curtis's TEXTBOOK OF GYNECOLOGY (London: W. B. Saunders, pp. 755, 40*s.*) has been extensively revised. A quarter of this American book is allotted to anatomy and physiology, and there are ten sensible pages on history-taking and examination. He is both wise and dogmatic in advice, but never hesitates to state and discuss the alternative view to his own.

Prof. Robert Courrier has reviewed and examined published work on the physiology of gestation from ovulation to the puerperium (ENDOCRINOLOGIE DE LA GESTATION, Paris: Masson, pp. 339, fr. 465). His book also describes much French work, notably in comparative physiology, which has hitherto been insufficiently appreciated in this country. His book is well illustrated and is readily comprehensible to the English reader with a smattering of French.

In the 1946 YEAR BOOK OF EYE, EAR, NOSE AND THROAT (Chicago: Year Book Publishers, pp. 543, 21*s.*) chapters on the eye occupy about half the text, and are preceded by a special article on the medical treatment of glaucoma by Dr. Louis Bothman, who edits this section. The second half of the book is edited by Dr. Samuel J. Crowe, and includes 37 pages on war injuries of the ear, in which the long-term effects of treatment are now beginning to be assessed.

The sixteenth edition of Stedman's PRACTICAL MEDICAL DICTIONARY (London: Baillière, pp. 1201, 42*s.*) has been well edited and revised by Dr. Norman Burke Taylor, and has acquired a welcome section on medical etymology by Mr. A. E. Taylor, which makes simple the translation of classical terms into familiar ones. Appendices give weights and measures, the meaning of symbols, comparative temperature and barometer scales, a table of elements, and the three forms of anatomical nomenclature which may still come the way of luckless students.

A POCKET SURGERY (2nd ed., London: J. & A. Churchill, pp. 272, 8*s.* 6*d.*) by Mr. P. H. Mitchiner, surgeon to St. Thomas's Hospital, and Mr. A. Hedley Whyte, surgeon to the Royal Victoria Infirmary, Newcastle-on-Tyne, is a comprehensive review of general surgery, useful for the Service medical officer who finds himself far from colleagues and libraries; but for the civilian doctor details are somewhat scanty. On specialised subjects the advice given is sometimes questionable—e.g., the recommendation to wrench the adolescent coxa vara into position, and to move sutured tendons on the second or third day. The sections on the broad principles of general surgery and on abdominal surgery are perhaps the best in the book.

PRINCIPLES OF ANATOMY AND PHYSIOLOGY FOR PHYSICAL TRAINING INSTRUCTORS IN THE ROYAL AIR FORCE (H.M. Stationery Office, pp. 180, 7*s.* 6*d.*) has been written with the primary object of explaining the basic facts of anatomy and physiology to members of the Royal Air Force interested in maintaining physical fitness, whether in men receiving routine physical training, or patients in hospitals, or at reablement centres. The anonymous authors have dealt with their subjects so clearly, and hold the reader's interest so well, that the general public and the medical student will also enjoy reading the book. The skeletal and muscular systems are of course particularly well covered; the remaining systems are treated under physiology. The pages on the pathology of malposture are very good, and all the illustrations are first-class.

The pages on the pathology of malposture are very good, and all the illustrations are first-class.

THE LANCET

LONDON: SATURDAY, MARCH 8, 1947

Enough to Eat?

DISCUSSION of the national diet, now a favourite pastime, is often silenced by a reminder that it is determined less by appetite than by world supplies and the requirements of other countries. When famine threatens Eastern Europe, it may seem indecent to grumble about dull food or minor deficiencies. Nevertheless both our allocation of existing supplies and our policy for the future depend partly on knowing how far we are in fact now being properly fed. A single theme runs through the Government's economic white-paper[1]—the need for greater production—and elsewhere in this issue Dr. McMENEMEY argues cogently that for full physical and mental health, and thus for full production, the national diet must be increased and varied.

The nutritionists tell us that the average consumption of the people of this country falls little short of what it was before the war; and that this consumption, though near the borderline, is still above internationally accepted minimal standards.[2] On the other hand, the margin is so small that inability to draw on the floating 10% of rationed foods at canteens or restaurants undoubtedly causes some to go short, and there is uneven distribution within the family.[3] The ration is not large enough to meet personal idiosyncrasies in favour of a particular food, and it takes little account of personal taste. Despite improvements, our fare remains monotonous, and whatever its other virtues it often fails to give the sense of satisfaction and repletion by which we tend to gauge the sufficiency of meals. Has this any adverse effect on personal efficiency? Surveys, we are informed, "suggest that the nutritional state of the nation was not worse at the end than at the beginning of the war, and, as regards children, was somewhat better." [4] But, as E. P. CATHCART [5] has put it, a person's state involves something more than physical attributes: "there are also intangible psychic factors which may be summarised in terms like 'alertness,' 'fitness,' 'aliveness,'" and these are not readily measured. The surveys have been few in number and restricted in scope, and wide differences in the conclusions of competent observers studying the same groups show how high personal judgment ranks in the reckoning.[6] Until a base-line has been found, the nutritionist can give no firm answer to those who ask whether there is particular virtue in good red meat, or to those others who suggest that we are getting a suboptimal diet whose defects are evident only in our daily work.

By all accounts, many of the peoples of Europe, on inferior rations, are showing remarkable vigour in reconstruction: the strength of their incentives seems to overcome the deficiencies of their food. Obviously, then, the nutritionist cannot expect to see the whole picture. To the psychologist many of the features which are physically baffling seem clearer. The prevalent hunger is, he argues, one manifestation of our gradual recovery from post-war inertia: it is related to a larger hunger for a sense of purpose and a sense of security; and the common syndrome of lassitude, irritability, and deficient mental concentration, tentatively ascribed by others to early vitamin-B deficiency, he claims to be at least partly psychogenic. He has satisfied himself of a relationship between food-fussiness and uncertainty or insecurity; and these are uncertain times. He reasons that the worker, particularly in industry, seeks to offset the lack of colour in his daily employment by variety and excitement in his relaxations; the present diet underlines, instead of interrupting, the general monotony. He points to examples in industry where, with low morale and reciprocal hostility between management and workers, the canteen is made a scapegoat. The current irritation could, he believes, be partly overcome by giving people more say in their feeding; he would promote open discussions, and he would ensure that workers were given evidence of attention to their diet and to the pattern and difficulties of their lives, for Service experience showed that a man's opinion of his food varies less with its quality at the table than with the interest known to be taken in its preparation and in his own general welfare. Finally, the psychologist would favour, as a form of mental release, any changes which brought greater variety, satiety, or acknowledgment of pet luxuries. How far advantages of this kind can properly be used as an incentive to enter particular industries, or as a reward for good output, is another matter. It depends perhaps on whether they would be offered at the expense of a satisfactory diet for the rest of the community; for in Lord BEVERIDGE's phrase, nobody should eat cake till everyone has bread, and hitherto it has been an acknowledged principle that in the distribution of food there should be no privileged class.

The control of food is not, of course, the concern simply of the dietitian, the nutritionist, or the psychologist. It concerns also employer and employed, those who grow or buy food, those who process or cook it, and those who distribute it; and each can make his own contribution. Five years ago the *Times* suggested that representatives of these various interests should be brought together in a Nutrition Council; but despite influential support, particularly from leaders of the medical profession, the council was never formed. This time of economic adversity might be the occasion to reverse the decision. One of the council's first tasks would be to undertake the continuous surveys recommended at the Hot Springs Conference, and such surveys might help, among other things, to answer the question whether the diet adequate to prevent any signs of malnutrition or disease is ipso facto adequate for full endeavour. To a country spending £725 million this year on imported food and agricultural equipment, and

Vitamin Therapy—its uses and limitations

EFFECTS OF VITAMIN B DEFICIENCY

Restricted intake of vitamin B has been shown to produce marked symptoms of moodiness, sluggishness, indifference, fear, decreased mental alertness and physical fatigue.

Factors of the vitamin B Complex have been found effective in many such cases. This, with other experimental and clinical work, indicates the value of an adequate vitamin B intake for preventing mental strain and physical fatigue and for preventing other ill effects of malnutrition which may still occur.

Oxford and Cambridge BOAT RACE (March 29)

We have space for a few doctors and friends at our Hammersmith Wharf. Please make early application for tickets.

BEFORTISS

B-complex capsules

Each capsule contains		
	Aneurin Hydrochloride	1.0 mg.
	Riboflavin	1.0 mg.
	Nicotinamide	15.0 mg.
	Pyridoxin	0.5 mg

Enough to Eat?

DISCUSSION of the national diet, now a favourite pastime, is often silenced by a reminder that it is determined less by appetite than by world supplies and the requirements of other countries. When famine threatens Eastern Europe, it may seem indecent to grumble about dull food or minor deficiencies Nevertheless both our allocation of existing supplies and our policy for the future depend partly on knowing how far we are in fact now being properly fed. A single theme runs through the Government's economic white-paper [1]—the need for greater production—and elsewhere in this issue Dr. MCMENEMEY argues cogently that for full physical and mental health, and thus for full production, the national diet must be increased and varied.

The nutritionists tell us that the average consumption of the people of this country falls little short of what it was before the war, and that this consumption, though near the borderline, is still above internationally accepted minimal standards [2] On the other hand, the margin is so small that inability to draw on the floating 10% of rationed foods at canteens or restaurants undoubtedly causes some to go short, and there is uneven distribution within the family.[3] The ration is not large enough to meet personal idiosyncrasies in favour of a particular food, and it takes little account of personal taste. Despite improvements, our fare remains monotonous, and whatever its other virtues it often fails to give the sense of satisfaction and repletion by which we tend to gauge the sufficiency of meals. Has this any adverse effect on personal efficiency? Surveys, we are informed, "suggest that the nutritional state of the nation was not worse at the end than at the beginning of the war, and, as regards children, was somewhat better." [4] But, as E. P. CATHCART [5] has put it, a person's state involves something more than physical attributes: "there are also intangible psychic factors which may be summarised in terms like 'alertness,' 'fitness,' 'aliveness,'" and these are not readily measured The surveys have been few in number and restricted in scope, and wide differences in the conclusions of competent observers studying the same groups show how high personal judgment ranks in the reckoning.[6] Until a base-line has been found, the nutritionist can give no firm answer to those who ask whether there is particular virtue in good red meat, or to those others who suggest that we are getting a suboptimal diet whose defects are evident only in our daily work

By all accounts, many of the peoples of Europe, on inferior rations, are showing remarkable vigour in reconstruction: the strength of their incentives seems to overcome the deficiencies of their food. Obviously, then, the nutritionist cannot expect to see the whole picture. To the psychologist many of the features which are physically baffling seem clearer. The prevalent hunger is, he argues, one manifestation of our gradual recovery from post-war inertia: it is related to a larger hunger for a sense of purpose and a sense of security; and the common syndrome of lassitude, irritability, and deficient mental concentration, tentatively ascribed by others to early vitamin-B deficiency, he claims to be at least partly psychogenic. He has satisfied himself of a relationship between food-fussiness and uncertainty or insecurity; and these are uncertain times. He reasons that the worker, particularly in industry, seeks to offset the lack of colour in his daily employment by variety and excitement in his relaxations; the present diet underlines, instead of interrupting, the general monotony. He points to examples in industry where, with low morale and reciprocal hostility between management and workers, the canteen is made a scapegoat. The current irritation could, he believes, be partly overcome by giving people more say in their feeding; he would promote open discussions, and he would ensure that workers were given evidence of attention to their diet and to the pattern and difficulties of their lives, for Service experience showed that a man's opinion of his food varies less with its quality at the table than with the interest known to be taken in its preparation and in his own general welfare. Finally, the psychologist would favour, as a form of mental release, any changes which brought greater variety, satiety, or acknowledgment of pet luxuries. How far advantages of this kind can properly be used as an incentive to enter particular industries, or as a reward for good output, is another matter. It depends perhaps on whether they would be offered at the expense of a satisfactory diet for the rest of the community; for in Lord BEVERIDGE's phrase, nobody should eat cake till everyone has bread, and hitherto it has been an acknowledged principle that in the distribution of food there should be no privileged class.

The control of food is not, of course, the concern simply of the dietitian, the nutritionist, or the psychologist. It concerns also employer and employed, those who grow or buy food, those who process or cook it, and those who distribute it; and each can make his own contribution. Five years ago the *Times* suggested that representatives of these various interests should be brought together in a Nutrition Council; but despite influential support, particularly from leaders of the medical profession, the council was never formed. This time of economic adversity might be the occasion to reverse the decision. One of the council's first tasks would be to undertake the continuous surveys recommended at the Hot Springs Conference, and such surveys might help, among other things, to answer the question whether the diet adequate to prevent any signs of malnutrition or disease is ipso facto adequate for full endeavour. To a country spending £725 million this year on imported food and agricultural equipment, and urgently needing greater output, this question is highly important; but if nutrition continues to be regarded as a matter for guidance exclusively by nutritionists, and for purely interdepartmental discussion, we shall not be making full use of our opportunities to get the facts.

Part-time Nursing and its Future

DURING the war it was often said that part-time nursing had been tried but had failed. Gloucestershire has made it clear that the failure lay not with the part-time workers but with those seeking to use them. Those who attended the Cheltenham conference (reported elsewhere in this issue) saw hospitals, staffed almost entirely by part-timers, running smoothly and giving to chronic-sick patients a standard of care not exceeded in first-class acute hospitals.

In his full account of an experiment for which he has been largely responsible, Mr. W. A. SHEE could not help revealing how much careful and human deliberation had gone to make it succeed. The essence of the scheme has been *that part-time workers*, whether State-registered nurses or raw recruits with no previous experience, have been regarded from the beginning as members of the hospital team, and given responsibility appropriate to their sense and experience. The result has been to attract a new type of woman into nursing, or rather to attract good nurses who have been compelled to resign their career, and *other able women who can give some but not all of* their time to the care of the sick. There seems little doubt that we now have in our hands a complete answer to the staffing difficulties of the infirmaries and institutions for the old and ailing, and the Ministries of Health and Labour are warmly encouraging local authorities to follow Gloucestershire's lead. The many visitors to the conference went back convinced, to carry the principles to their own areas. Medical officers of health were not perhaps as numerous as could have been wished, but possibly the Society of Medical Officers of Health would contemplate inviting Dr. KENNETH COWAN and Mr. SHEE to open a discussion on part-time nursing at one of their meetings. The success of such schemes, experience has shown, depends on overcoming in advance the prejudice of those who will have to work it, and especially the prejudices of matrons; and nobody is better placed for this persuasive task than the medical officer of health. The prejudices of authorities can be diminished by showing the Gloucestershire balance-sheet, where expenditure of £10,000 a year on transport is entirely compensated in other ways.

Londoners will have noticed that a part-time scheme was launched on Feb. 15 for the Greater London area, where the L.C.C. hospitals are in greatest need. The daily press has published lists of hospitals to which volunteers can apply; the Ministry of Labour resettlement advice offices are also taking particulars from volunteers and forwarding them to the nearest hospital wanting part-time workers; and specially difficult cases are being put through the London Appointments Office, at 23, Portman Square, W.1, which is acting as a clearing-house for the whole area. The appeal unfortunately coincided with the fuel crisis, and this no doubt *partly* explains why the number of volunteers of all kinds in a fortnight was only 930—a total which must seem meagre to those familiar with the Cockney tradition of lending a friendly hand to neighbours in difficulties. But *criticisms at the conference suggest that backwardness* in volunteering is also partly attributable to the Rushcliffe rates of pay which have been adopted. On this scale intermediate assistant nurses are paid 1*s*. 5*d*. an hour, which is less than the rate recommended by the National Joint Council for ward orderlies doing domestic work; and State-registered staff nurses are offered 2*s*. 1*d*., which is less than the average pay of a metropolitan charwoman. There was a strong feeling at the conference that these rates should be reconsidered.

May not the part-time principle have much wider applications than at present appear? Speakers at Cheltenham felt it opened great possibilities for *mental hospitals and sanatoria, and perhaps also* for special hospitals and acute general hospitals. There were doubts whether it could be applied in training schools, but further experiment may disperse even these: it is possible to conceive of a training hospital in which part-time workers, jointly with full-time trained staff, ensure the staffing of the ward, and thus release the sister for bedside teaching and the students for learning. The long-standing complaint that students bear the double burden of study and hospital service could thus be relieved. We must not be faint-hearted if the implications of the part-time system turn out to be much greater than we originally supposed.

Neonatal Infection

IT is probably fair to say that about a fifth of all deaths in the first four weeks of life are the result of infection. Rather more than half of the total infant mortality occurs in this first month, which in England and Wales means some 18,000 deaths; so each year 3000–4000 babies die of infection, much of it preventable, in the first few weeks of life. The report[1] of a subcommittee of the Scottish Scientific Advisory Committee, under the chairmanship of Sir ALEXANDER MACGREGOR, which has been studying the causes, predisposing factors, and control of neonatal infection, shows that the neonatal mortality for Scotland during 1941–43 was 35·91 per thousand live births. The rates for maternity units ranged from 10·1 per thousand in emergency hospitals taking only normal cases to 52·2 per thousand in teaching institutions which admit a high proportion of abnormal cases and have a premature-birth rate of 12·7% compared with 2·8% in the emergency hospitals. The proportion of these deaths attributed to infection ranged around 10%, but where clinical diagnosis was checked by careful post-mortem examination this proportion was doubled.

The principal form of fatal neonatal infection was pneumonia, of which Dr. AGNES MACGREGOR has described four main varieties. The first is chiefly associated with birth asphyxia, and deaths usually occur in the first three days of life; its prevention lies chiefly with the obstetrician. The second, septic aspiration pneumonia, also most common in the first few days of life, is due to inhalation of milk or regurgitated stomach contents; its prevention is dependent on care in the feeding and nursing of the infant. The third, staphylococcal pneumonia, is commoner in the neonatal period than at any other time of life and frequently arises in small outbreaks: while the fourth, bronchopneumonia similar to that in older infants, may be due to organisms, such as *Bact. coli.* which are not usually associated with pneumonic infection. Many of these pneumonias, which are most common in premature infants and are often related to faults in lung function, are undetected clinically because of the absence of cough, fever, and dyspnœa; while cyanosis, when present, may suggest asphyxia or cerebral hæmorrhage. In Scotland, in the three years covered by the report, neonatal diarrhœa was responsible for much fewer deaths than respiratory infections, and outbreaks of neonatal diarrhœa were rare, but the committee cite Prof. CHARLES MCNEIL's figures showing an incidence of diarrhœa ten times higher in premature than in full-time babies. The committee also comment on the much greater resistance to intestinal infection among breast-fed than among artificially fed infants, a point well illustrated by the figures from Cincinnati,[2] where of 221 infants admitted to hospital for diarrhœa all but 3 had been bottle-fed.

---

[1] Neonatal Deaths Due to Infection. Edinburgh: H.M. Stationery Office. 1947. Pp. 43. 9*d*.

The committee give sound advice on prevention. Emphasis is rightly laid on the adequacy and quality of the nursery nursing staff. They should be sufficient in number for the work to be careful and unhurried; there should be a nucleus of permanent trained staff to ensure continuity of treatment; and a basic nursing technique should be fully understood and practised. The nursery nurse or "auxiliary worker" (who may range in age from 17 to 45 years), being a permanent member of the nursing staff, is more useful than the pupil-midwife who spends only 4–6 weeks in the nursery. The nursery should be under the charge of a pædiatrician skilled in the care of young babies, and records should be kept of the day-to-day progress of each infant so that any minor infection or loss of weight is noted and attended to early. Mothers need more instruction in the care of the infant and in breast-feeding, WALLER's[3] studies on lactation being borne in mind; this may mean a larger staff and a longer stay in hospital, and, before the mother leaves hospital, coöperation between the health visitors and the hospital midwives. The committee were divided in their views about keeping infant and mother together or having a separate nursery for the healthy babies. If separate nurseries are provided they should be small, containing only 4–6 cots and allowing 40 sq. ft. per cot; the cots should be properly spaced and not crowded cheek by jowl along one side of the room as they often are. A separate nursery with a number of single rooms should be provided for sick and premature infants and for infected cases requiring isolation. For premature infants the committee favour a ward unit of 4 cots kept at a temperature of 75–80° F and a relative humidity of 70%, and they recommend the nursing technique evolved by Dr. MARY CROSSE in Birmingham.

Prematurity is clearly the most important predisposing factor in fatal infections. Thus in the two largest Scottish teaching hospitals the death-rates from infection were 5·4 and 5·7 per thousand among mature babies but 79 and 75 per thousand among premature infants. In the four Glasgow corporation hospitals, where the proportion of abnormal cases is much smaller, death-rates from infection among full-time and premature babies were 3·4 and 29 per thousand. Of the neonatal deaths from all causes, 70% were in premature infants. The causes of prematurity require further elucidation, but the studies of BAIRD[4] and SUTHERLAND[5] indicate that poverty and poor nutrition of the mother are important factors, and the remarkable reduction in the stillbirth-rate and neonatal mortality during the war years is probably a reflection of better nutrition in the lowest social classes, among whom premature births are most common. A reduction in the prematurity-rate, now around 7%, must be the long-term policy in the control of neonatal mortality. Meanwhile, this report points the way to the preventive measures that should be practised in every maternity unit.

Annotations

DIVORCE

THE great argument against divorce is the bad effect of a broken home on children. In their final report,[6] the Committee on Procedure in Matrimonial Causes, whose chairman is Mr. Justice Denning, pay special attention to the child, and consider in detail possible means of reconciling the parents. Reconciliation work has so far been mostly done by voluntary bodies, some of them religious. Court missionaries and probation officers have also helped estranged couples to understand each other better, and so have the Family Welfare Association, and the Sailors', Soldiers' and Airmen's Families Association. Since 1937 magistrates have been officially permitted to ask a probation officer or other person to try to reconcile parties seeking separation or divorce. Under the Army and R.A.F. Legal Aid Scheme some 27,000 applicants for divorce (a quarter of all those applying) have been reconciled; and in civilian life the Marriage Guidance Council, founded in 1938 and reconstituted in 1943, has done successful work. At its centres selected people act as "counsellors," interviewing those who apply and often referring them, according to their needs, to a consultant, who may be a doctor or psychologist, an ethical or spiritual adviser, a social worker, or a lawyer.

The Denning Committee find that the prospects of reconciliation are most favourable in the early stages of disharmony, and in families where there are children. For success, one of the couple must seek help of his or her own free will; and each must be sure that nothing told to the adviser will be repeated to the other partner without permission. The personal relationship with the adviser is so important that churches, voluntary societies, and individuals have a much better chance than a State institution would. Unfortunately the law relating to collusion and condonation hampers attempts at reconciliation: fear that the divorce may be quashed makes each partner reluctant to offer or accept advances. Actually, the law about collusion does not forbid discussions with a view to reconciliation, or about the future of the children, the house and furniture, maintenance, or costs. Condonation, on the other hand, presents a more serious bar to reconciliation, because one act of sexual intercourse cancels out an injured husband's grounds for divorce (though it does not affect those of an injured wife unless she has really forgiven and reinstated her husband).

[6] Cmd. 7024. H.M. Stationery Office. Pp. 36. 9d.

The committee want to see a Marriage Welfare Service, sponsored by the State, established to ensure that enough suitable advisers are available, to encourage people to seek competent advice—engaged couples in preparation for marriage, and married couples as soon as serious conflicts arise—and to attempt reconciliation when necessary. This service would be developed from existing services and societies, which would be grant-aided, and would have opportunities for broadcasting, and for giving information at registrars' offices. Court welfare officers would be appointed to help those applying for divorce, or thinking about it; and solicitors approached about divorce would be asked to recommend the couple to consult a welfare officer or one of the voluntary societies. The welfare officer should have access to every petition, and in suitable cases should write offering his services.

The committee think that the present administration of divorce is poorly fitted to safeguard children.

> If no application is made for custody, the court has no opportunity to consider their welfare; if an application for custody is unopposed, the court usually grants it; though the lack of opposition may be due to misunderstanding. Thus a wife who is guilty of adultery may think she has forfeited the children and may reluctantly hand them over to her husband, though this may not be the best thing for them. Where an application is opposed, the subsequent conflict between the parents often becomes so bitter that the welfare of the children fades out of sight.

The report recommends that in every divorce case, whether there is an application for custody of the children or not, the court welfare officer should report on the welfare of the children and should represent their interests before the court. The divorce judge should deal with the future of the children on the same day as he deals with the divorce, but afterwards. The hearing about custody should be in private, and the parents and their advisers would have the chance to be present, and to bring witnesses: their evidence should be given orally on oath, and not by affidavit as at present. The judge would also be able to see the parents and children separately and in private.

The rest of the committee's recommendations deal with alimony and maintenance, and with procedural reforms to meet certain difficult cases. These have no direct bearing on social medicine.

CONTROL OF SCRUB-TYPHUS

In the Far East campaign scrub-typhus was a major medical problem whose dimensions had not been anticipated from the limited peace-time experience. Only when the jungle was invaded by an army was it realised how widespread was the infestation. This mysterious disease had a profound effect on the fighting soldier and it acquired some of the properties of a secret weapon. The overall case-mortality of about 10% was equally impressive to the medical authorities. Owing to the painstaking work of Australian investigators and the U.S. Typhus Commission the disease came ultimately under complete control.

In attacking this problem McCulloch[1] assumed that the disease was mite-borne—a view widely held at the outbreak of war and one which has since been further substantiated. The success of new mosquito repellents such as dimethyl phthalate suggested their use against the trombiculids which carry the rickettsia responsible for scrub-typhus. The field work began with the exposure of volunteers to the mite producing "scrub itch," *Trombicula minor*, a mite which does not carry the rickettsia but produces the same reaction as the "harvester" mite in England. The protection afforded by dimethyl phthalate was striking, and dibutyl phthalate (D.B.P.)—more readily obtainable in Australia—proved even superior and withstood washing without losing its repellent action. With this initial success the detailed treatment of clothing was worked out on sample pieces of cloth subjected to various forms of impregnation and various types of washing, using mites easily obtained from the jungle. The method eventually adopted by Australian troops was to rub an ounce of D.B.P. into socks, trousers, and shirt once a fortnight, a treatment which was shown to be effective even with unrestricted washing. Rubbing in by hand was much better than spraying.

One of the most important and difficult stages in the introduction of new hygiene measures to a field force is the necessary education of the soldier, who is sceptical and suspicious of innovations. This "sales-resistance" disappears directly a unit encounters scrub-typhus in the field, and unit commanders then become anxious to take advantage of any method of protection. In New Guinea the instruction of troops formed one of the most important elements of success. Anti-mite fluid was first issued to the Australian forces in November, 1943, and by June, 1944, all troops in forward areas—those most exposed to infection—were protected. The scrub-typhus rates fell sharply. For the last year of the war the incidence was about 9% of that for 1943, though this fall cannot wholly be ascribed to the use of the miticide, since distribution of scrub-typhus is essentially patchy and troops may have been fighting in less infested country. However the unmistakable conclusion of the New Guinea campaign was that D.B.P., applied fortnightly, could completely control scrub-typhus and that where failure occurred it was ascribable to lack of supplies.

A NEW DIPHTHERIA PROPHYLACTIC

ALUM-PRECIPITATED toxoid (A.P.T.), the diphtheria prophylactic used in this country for mass immunisation, is doing much to prevent this preventable disease, as the Ministry of Health figures and the depleted diphtheria wards in fever hospitals combine to show. Yet though A.P.T. is potent and generally reliable, it has some drawbacks. Thus, as Mr. Holt points out on another page, it is difficult to prepare batches of uniform antigenicity because its exact composition is uncertain, and we still do not know how precipitation enhances the activity of the toxoid, and what influence impurities have on the antibody-response. These defects have, in his opinion, made the assessment of dosage and spacing unsatisfactory. He has therefore devised a new prophylactic believed to be antigenically potent and stable and productive of fewer reactions than A.P.T. in sensitive persons. It consists of purified toxoid precipitated by a suspension of a measured amount of purified aluminium phosphate ($Al PO_4$) and is called P.T.A.P. The great advantage claimed for it is that the antigenicity of each batch can be accurately predicted.

The new product has been submitted to field trials on a pilot scale by Dr. Guy Bousfield, who reports on his results in this issue. The subjects were Schick-positive children between their first and second birthdays, living in a suburban area where herd-immunity was low; thus the children were of reasonably comparable body-weight and without substantial basal immunity. Serum antitoxin titrations were thought to be impracticable in these young children, so Dr. Bousfield assessed the immunity responses to a single subcutaneous injection of the prophylactic by post-Schick tests carried out 28 days later. Breaking new ground, and seeking to avoid undesirable reactions, the trials were made in stages, in an attempt to determine the optimum concentration of $Al PO_4$ and Lf dosage of toxoid. The highest Schick-conversion rate (93%) was obtained with 5 Lf units of toxoid in conjunction with 5 mg. of Al PO$_4$. Small though the series were, the results seem to demonstrate the favourable effect on the Schick-conversion rate of increasing the amount of Al PO$_4$ up to this level, and the importance of controlling the amount so as to obtain an optimal primary stimulus. Further tests are to be made to determine more exactly the dosage of Al PO$_4$ which produces the best results.

---

[1] McCulloch, R. N. *Med. J. Aust.* 1946, i, 717.

When A.P.T. is injected intramuscularly nodules sometimes form at the site of injection, unless it is made deeply. Dr. Bousfield found at the time of the post-Schick tests that nodules could often be felt where P.T.A.P. had been injected subcutaneously, and that their incidence rose almost in strict proportion to the increase of the Al PO$_4$ content. His findings support the view that satisfactory primary stimulation depends on some degree of local fibrosis and depot-action—that is, the slow release of toxoid into the tissues generally. Thus the nodule which some workers have sought to avoid by a suitable technique of injection may be an important factor in the production of immunity. General reactions after the subcutaneous injections of P.T.A.P. were few; and after a subsequent intramuscular dose to complete the immunising course there were none at all.

Since the choice of a new prophylactic for mass-immunisation is of national concern, these observations will doubtless be repeated by other workers on a bigger scale. In such trials the results—with due respect to Schick's test—should be additionally checked by antitoxin titrations.

JANET

Pierre Janet's great contribution to psychopathology showed two dominant trends, happily fused. On the one hand he was a collector and systematist, in the Linnæan tradition: all his life he went on adding to the fine herbarium which he began in childhood, and the patient amassing of exact data about mental abnormality was only another activity of the born collector-classifier. The other side of him—mystical and philosophical—was equally strong, though less in evidence; to it he attributed his first interest in psychology and especially in clairvoyance and hypnotism, the study of which brought him, when he was 23, to the notice of Charcot and Richet in Paris, and incidentally of Sidgwick and F. W. H. Myers in the Society of Psychical Research in London. His appointment in 1889 to the charge of the psychological laboratory which Charcot established at the Salpêtrière set his feet firmly on the path which he followed for the next half century with endless zest and exactitude. He used to say that his was a "psychology of the fountain pen" so careful was he to record immediately and with minute fidelity what the patient and he had said, and to abstain from using any recollections that were not precisely in accord with what he had set down in his voluminous notes. His medical training made him reluctant to generalise from particular observations, or to stress dynamic psychological influences at the expense of the hereditary and organic causes of mental illness. Consequently, although he had observed the significance of traumatic experiences and the occurrence of unconscious mental processes earlier than Breuer and Freud, he stopped short at this observation; writing of it much later, he said he could not expand a clinical observation into a metaphysical system. The notions of psychological tension and mental level which he introduced served him well in describing the functional hierarchy and the play of symptoms in the neuroses. In England his concept of dissociation and his descriptions of "psychasthenia" are more widely known than his far-reaching studies into the psychology of conduct, which have become part of orthodox French psychiatry. The essence of his later work lay in the effort to classify all psychological facts under action and conduct, in accordance with his notions of hierarchical organisation. The economic problems of action, the sources and expenditure of energy, seemed to him the paramount issue in psychology and psychiatry. Whereas the methods and the theories of the other great psychopathologist who was his fellow-student at the Salpêtrière were revolutionary, Janet had a classical preference for precision and order: he subordinated hypothesis to exact observation, and his teachings aroused neither the antagonism nor the productive stir that made Freud the greater force.

TONICS VINDICATED?

THE vegetable "tonics" have long been out of fashion in our medical schools—at most they have achieved passing mention in historical introductions to pharmacology—yet the family doctor has continued to prescribe some of them for their appetising properties or merely as flavouring agents. Now it seems that there may be a rational basis for these traditional remedies. Chaikelis[1] has investigated the thiamine content of 41 genera of herbs and medical plants belonging to 20 distinct and separate botanical families, and has found that this ranges from 125 to 2880 microgrammes per 100 grammes of dried substance. No less than 12 of the dried plants examined contained more than 1000 µg. per 100 g. and only 5 contained less than 300 µg. The list includes buchu (1965 µg. per 100 g.), caraway (722), camomile (1154), dandelion (1577), gentian (477), quassia (1839), thyme (502), and white cinnamon (427). The two richest known sources of thiamine, wheat-germ and yeast, contain 2000 µg. per 100 g., so some of these herbs run them close. It would be interesting to know how much of the thiamine content of herbs is extracted in making infusions. Chaikelis points out that the symptoms of thiamine deficiency include loss of appetite, fatigue, gastro-intestinal disturbances, muscular weakness, and lowering of the blood-pressure, and these are the very symptoms for which tonics are often prescribed.

NEGOTIATIONS BEGIN

ON Friday of last week the Negotiating Committee, representing medical organisations, met the Minister of Health for discussions on the National Health Service Act. The members now are:

British Medical Association.—Nominated by the council: Dr. J. A. Brown, Dr. R. W. Cockshut, Dr. Guy Dain, Dr. W. E. Dornan, Dr. F. Gray, Dr. E. A. Gregg, Mr. R. L. Newell, Dr. S. Wand, and a Scottish member. Elected by the representative body: Mr. A. Lawrence Abel, Dr. J. C. Arthur, Dr. O. C. Carter, Lord Horder, Dr. J. A. L. Vaughan Jones, Dr. J. F. Lambie, Dr. J. B. Miller, Dr. J. A. Pridham, and Dr. S. A. Winstanley.

Royal College of Physicians.—Lord Moran, Dr. H. E. A. Boldero, and Prof. Henry Cohen.

Royal College of Surgeons.—Sir Alfred Webb-Johnson, Mr. Zachary Cope, and Prof. Ernest Finch.

Royal College of Obstetricians and Gynæcologists.—Mr. William Gilliatt and Mr. A. A. Gemmell.

Royal Scottish Medical Corporations.—Prof. Charles McNeil, Mr. Henry Wade, and Dr. J. H. Macdonald.

Society of Medical Officers of Health.—Dr. G. F. Buchan and Dr. R. H. H. Jolly.

Medical Women's Federation.—Dr. Mary Esslemont.

Society of Apothecaries.—Dr. H. Seaward Morley.

The committee has set up six subcommittees dealing severally with general practice, hospital and specialist services, public health, mental-health services, eye services, and superannuation.

Sir WILL SPENS is to preside over a committee to consider the remuneration appropriate for consultants and specialists in a publicly organised service.

---

RECRUITMENT OF DOCTORS TO THE FORCES

REPORT FROM THE CENTRAL MEDICAL WAR COMMITTEE

THE Central Medical War Committee (C.M.W.C.) has issued an account of the work of its Services Committee during 1946. The report, signed by Mr. H. S. SOUTTAR, chairman of the C.M.W.C., and by Dr. PETER MACDONALD, chairman of the Services Committee, begins by describing the constitution and function of these bodies.

The C.M.W.C. is reappointed annually by the Minister of Health. Its members are nominated by various professional organisations and other bodies. The Services Committee, which is concerned with the recruitment of individual practitioners and acts generally as the executive of the C.M.W.C., is reappointed annually by the parent committee, chiefly from its own membership; it includes four ex-Service doctors, three of them specially appointed as such. The members of both committees give their services voluntarily. Officers of the three Service departments and of the Ministries of Health, Labour, Education, and Pensions attend all meetings as observers and advisers.

The functions which the Services Committee undertakes on behalf of the C.M.W.C. are advisory. The decisions of the committee are recommendations to the Minister of Health, who acts as the agent of the Minister of Labour and National Service so far as the recruitment of doctors is concerned. As a general rule, however, these decisions receive the tacit consent of the Minister's representatives who attend the meetings, and are put into effect without first being submitted formally to Whitehall for approval. In practice, therefore, the committee acts as if it had executive powers; but the last word always rests with the Minister of Health; in matters of general policy the committee can only recommend. The answer to those critics who blame the committee for not raising the limit of age for compulsory recruitment of specialists, or for not calling up men rejected during the war as medically unfit for service, or for not forecasting the release of age-service groups of serving officers for at least six months ahead is that the committee is not in a position to do any of these things. Although the release arrangements depend partly on the success of its efforts to obtain new recruits, the committee does not determine these arrangements and is never able to announce them until they have been promulgated by the Service departments.

RECRUITMENT OF GENERAL-DUTY OFFICERS

During the second half of 1945 the committee had recruited specialists up to the age of 40 and general-duty officers up to the age of 35. Early in 1946 the Government decided to retain the age-limit for specialists at 40 but to reduce that for general-duty officers to 30. Any man born on or after July 1, 1915, was to be regarded as within the latter age-limit. Within the last year the date of birth used in deciding liability for service has twice been advanced by six months for the purpose of maintaining the age-limit at 30. At the present time the date is July 1, 1916, the corresponding date for specialists being July 1, 1906.

During 1946 the committee had no difficulty in supplying the quotas of general-duty medical officers allotted to the three Services on the recommendation of the Medical Personnel (Priority) Committee, now known as the Medical Priority Committee. On the contrary, the number of practitioners, not of specialist status, who became available for recruitment during the year exceeded the estimates on which the quotas were based, with the result that the quotas had to be adjusted to take in the surplus. The total number of medical officers recruited for general duty was 1123. This figure is considerably higher than the corresponding figure (968) for the previous year, and is not much below the figure (1185) for the year 1944, when the limit of age for compulsory recruitment was much higher than in 1946 and when women doctors were still liable to such recruitment and were in fact recruited to the number of 200. The increased yield of recruits in 1946 is to be attributed to the fact that large numbers of ex-Service doctors became available during the year for civilian employment. The result of this was that recently qualified practitioners had greater difficulty in obtaining B2 and B1 hospital posts and thus securing deferment of call-up, and those already holding B1 posts could more easily be released for military service.

The only difficulty encountered by the committee in connexion with recruitment of general-duty officers was in regard to the proportions in which the available recruits should be allotted to the three Services to enable them to release serving officers at approximately the same rate.

At the beginning of the year medical officers in the Royal Air Force were complaining bitterly about the arrangements for their release. Although the Army had announced its intention of releasing in February general-duty medical officers in group 38, and the Navy had already released some medical officers in group 40, the R.A.F. programme provided only for the release of group 28 by the end of March. The committee, although in no way responsible for this state of affairs, was being blamed for having failed to prevent what was alleged to be a departure from the Government's release plan. It was known that no medical recruits had been sent to the R.A.F. during the last four months of 1945, and this was being attributed to lack of foresight on the part of the committee, which had had no alternative but to allocate all the recruits available during these months to the Navy and the Army in accordance with Government instructions.

The Ministry of Health was asked to explain the situation, and replied that the inequality in the rates of release was an inevitable consequence of a decision of the Government, which had been announced in the House of Commons in December, 1945, to reduce the ratio of medical officers to Service personnel to 2 per 1000 in each of the three Services as an emergency measure. It was because the ratio of doctors in the R.A.F. had been relatively low that the numbers to be released from that Service were less than in the other Services. The Ministry added that there was no question of a departure from the white-paper plan, which was elastic enough to permit the release of different groups as between the three Services or indeed as between branches of each Service.

The white-paper had indeed stated that there would be necessary differences in the rates of release; but the committee was not satisfied that this particular case was one of necessity. It thought that equality could be achieved, although not immediately, by an adjustment of the quotas of recruits allocated to the three Services. It had been estimated that 450 recruits would be available during the first half of the year, and the number provisionally allocated to the R.A.F. on the advice of the Medical Priority Committee was only 110. The Services Committee recommended that this allocation should be increased materially, and was later informed that it had been increased to 210. When it became evident that the number of recruits in the first half-year would considerably exceed the estimate, the committee decided to allocate the greater part of the surplus to the R.A.F., which received 298 out of the total of 585.

The figures for the whole year are: Royal Navy, 145; Army, 410; Royal Air Force, 568. The quotas recommended by the Medical Priority Committee for the second half of the year were designed to bring R.A.F. releases into line with those of the Army by the end of the year. This result has been achieved, both Services having released group 53 in December.

RECRUITMENT OF SPECIALISTS

At the end of 1945 the release of specialists had already fallen behind the release of general-duty officers, and the difficulty of finding substitutes for those Service specialists who could not be released without replacement was causing the committee grave concern. The recruitment of specialists and graded specialists continued to be the most difficult problem confronting the committee during 1946. The ways in which it attempted to solve the problem are described briefly as follows:

In the first place, the committee examined a complete list of those specialists who had been granted deferment by the local medical war committees. Holders of B1 posts were excluded from the list as arrangements had been made for their recruitment to be initiated centrally and not by the local committees. Hygiene specialists, psychiatrists employed in the mental-hospitals service, and pathologists were excluded also, the nomination of recruits in these categories being in the hands of the Ministry of Health, the Board of Control, and the Medical Research Council respectively. Of the 135 specialists included in this list, some had been found medically unfit for military service; others were engaged exclusively in specialties in which recruits were not required; a few were found on further inquiry to have no liability under the National Service Act; and one was registered as a conscientious objector. There remained 80 possible recruits. These were mainly men between the ages of 35 and 40 who were performing highly important work, many of them being on the staffs of teaching hospitals. In rather more than one-half of these cases the committee resolved to initiate recruitment, but there were some cases in which it later decided, after examining the representations received, that it was necessary to grant further deferment; and a few of the men nominated eventually to the Service departments were rejected as medically unfit. The number of fit men whom the committee finally decided to recruit was 33. The scrutiny of these difficult cases entailed much labour, but enabled the committee to satisfy itself completely as to the very formidable problems with which the local medical war committees had been confronted in their efforts to find additional recruits among the few senior specialists of military age who had not already served in the Forces.

Holders of B1 posts have recently formed, and must continue to form, the great bulk of the new recruits of specialist and graded specialist status. In their review the committee re-examined also the position of those senior B1 officers who had previously been granted indefinite deferment because of the extreme difficulty of securing sufficiently experienced substitutes to take over their work. There were 25 such practitioners, of whom the committee decided to recruit 14. The other cases of specialists in B1 posts which were considered during the year—on the completion of twelve months or two years in the posts, or on the expiry of an extended period of deferment previously granted—numbered approximately 110; and in all but 16 of these cases the decision was to recruit the practitioners concerned, either immediately or after a short interval. In a further effort to increase the yield of specialist recruits the committee examined its register of general practitioners below the age of 40 and selected those practitioners who, because they held higher diplomas or for other reasons, possibly might be regarded as eligible for specialist or graded specialist status in the Forces; but in only 10 of these cases did the committee find it possible to initiate recruitment.

STANDARDS OF GRADING

During the past year the committee has modified greatly the standards used in classifying prospective recruits as specialists and graded specialists. Every recruit who has held a B1 post for not less than twelve months is now considered by the subcommittee concerned with grading. A candidate for grading is no longer expected to hold a higher diploma or to have been qualified for a specified number of years; the only question considered is whether he has acquired sufficient experience in a specialty to enable him to hold a responsible post in that specialty, under supervision in the case of a graded specialist. The supply of graded specialists has thus been appreciably increased. As there is now no shortage of general-duty recruits, the present policy of the committee is to allow a B1 officer to retain his post after he has held it for twelve months if he is not then considered eligible for graded specialist status but seems likely to qualify for such status after a further period of deferment.

The committee has repeated its request that the War Office should consider employing specialists of a lower physical standard. The War Office has been furnished with a list of the specialists rejected as medically unfit and has been asked to indicate which of these it is prepared to re-examine. Another recommendation made by the committee was that the Service departments should encourage voluntary recruitment by offering specialists a higher rank, but this proposal has been rejected as impracticable. Towards the end of the year the committee published an appeal to suitably qualified women doctors to offer their services as gynæcologists, anæsthetists, pathologists, and radiologists. Finally the committee has urged, not for the first time, the importance of scrutinising the use made by the Services of their specialist officers; and the Medical Priority Committee has recently sent investigators to conduct such a scrutiny in the main overseas commands with a view to economies in the employment of specialists.

The total number of specialists and graded specialists supplied to the Services during 1946 was 293, the corresponding figures for 1944 and 1945 being 46 and 80 respectively. Of the 1946 recruits, 17 were nominated by the Scottish Central Medical War Committee and 86 by the Committee of Reference, which initiates the recruitment of specialists in London. Despite all the efforts made to increase the yield of specialist recruits, the release of specialists from the Army was 12 groups behind the release of general-duty officers at the end of the year. Unfortunately, specialists of military age who are medically fit for service and have not already served do not exist in the numbers that would be required to bring the release of Army specialists into line with that of general-duty medical officers.

SHORT-SERVICE EMERGENCY COMMISSIONS

At its first meeting in 1946 the committee was informed that approval had been given to a recommendation of the Medical Priority Committee that specialists should be employed in the Forces on a short-term basis. It had been decided that suitable specialists would be accepted for employment for eighteen months, the commission held being known as a "specialist short-service emergency commission."

It was intended that these commissions should be given to any specialists liable to compulsory recruitment between the ages of 30 and 40, as well as to those above the age of 40 who joined the Forces voluntarily. It was hoped that the offer of employment limited to eighteen months would attract specialists above the age of 40 who might hesitate to volunteer for an indefinite period; and at the time it seemed reasonable to make the short-service commissions available also to specialists recruited compulsorily, if above the limit of age for recruitment of the male population generally, especially as many of these recruits had been retained against their own wishes in E.M.S. and other civilian appointments during the war years and had shared some of the disadvantages of the Service doctors, particularly the disadvantage of being unable to establish themselves in permanent positions.

Before many months had passed, however, the committee began to have doubts about the wisdom of this part of the plan. There was practically no response to the appeal for volunteers, and the continued difficulty experienced by the committee in obtaining sufficient recruits of specialist status made it appear that the men accepted for short-service commissions in 1946 might complete their service at a time when some of the specialists recruited in 1945, although due for release, would have to be retained for a further period.

In July the committee asked the Medical Priority Committee to reconsider the plan; and it was informed in November that it had been decided to suspend forthwith the offer of short-service emergency commissions to specialists liable to compulsory recruitment.

MISCELLANEOUS

In November the committee decided to discontinue, for an experimental period of six months from Jan. 1, 1947, its control of the establishments of resident medical officers in hospitals. This decision was thought unlikely to result in a serious reduction of the number of recruits available for general duty in the Services. As many of the senior hospital posts are now held by ex-Service doctors the committee considered it desirable, in the interests of future recruitment of specialists, that hospitals should be free to create additional posts as circumstances might require. It has asked the hospitals to restrict new B1 posts to men known to be liable and medically fit for military service.

The committee received nearly 1200 applications for release of medical officers out of turn during 1945. As was to be expected, the number greatly diminished in 1946. Among the 120 cases considered during the year there were 47 in which the committee decided to recommend release in class B. In 38 cases—16 of specialists and 22 of general-duty officers—the recommendations were approved by the Service departments. In view of the serious shortage of specialists in the Services, the committee has continued to exercise great discrimination in regard to release of specialists in class B.

The committee has again asked the Service departments to consider granting leave, whenever possible, to medical officers stationed overseas who have applied for permanent appointments and have been selected for interview. The departments continue to regard this proposal as impracticable. The War Office pointed out to the committee that such a concession could not be restricted to doctors and that, if it were made available generally, a large part of the Army would be continually on the move to and from the United Kingdom.

In the interests of ex-Service practitioners, the committee decided in February, 1946, that it would not in future recommend the issue of entry permits to doctors from Eire, even if satisfied as to the necessity of filling the appointments for which such doctors might be selected, except where the hospital concerned (or the local medical war committee in the case of an assistantship in general practice) was able to assure the committee that every effort had been made without success to secure a candidate normally resident in this country. In July the committee was informed that women entering this country from Eire would no longer be subject to any restriction relating to employment; and in December the information was received that the Home Office was anxious to remove all "conditional landing" controls at the end of the year as it considered that the imposition of landing conditions could no longer be justified in the case of a citizen of Eire. The committee, in view of the reported unemployment among ex-Service doctors, felt bound to resist this proposal, and requested reconsideration of the advisability of retaining for the time being the restrictions on employment in this country of male doctors from Eire who have not served in the Forces.

RELEASES FROM THE ARMY

The committee has received the following statistics relating to releases of medical officers from the Army since June 1, 1945, when the reallocation of man-power scheme came into operation:

	Total	*Percentage of strength* (11,876) *at June* 1, 1945
Releases to Dec. 30, 1946:		
Class A	8846	74 48
Class B	222	1·86
Class C	42	0·35
Relinquishments	123	1·20
Invalidings	295	2·50
	9528	80·39
Intake, June 18, 1945, to Dec. 30, 1946	1007	8·48
Net release to civil life	8521	71·91

MENTAL HEALTH

AT the inaugural meeting of the National Association for Mental Health, held in London on Feb. 12, Mr. R. A. Butler, M.P., was elected president, Lord Feversham chairman, Lady Norman vice-chairman, and Sir Otto Niemeyer treasurer. The association has been formed by the amalgamation of the Central Association for Mental Welfare, the Child Guidance Council, and the National Council for Mental Hygiene—as recommended by the Feversham committee on voluntary mental health services.

Dr. Kenneth Soddy, medical director of the association, said he was particularly anxious that the aftercare scheme for ex-Service psychiatric casualties should be continued. The voluntary case-work service would still be valuable as an outrider to official services. Occupation centres for defectives, the care of delinquents, and surveys were among the other tasks now in hand. In child guidance the era of indoctrination had ended; now the problem was to catch up with the opportunities which were offered. There was need for more child-guidance clinics and more workers; and it was hoped that the universities would take their share in the training of these workers. An important international congress, organised at the request of international bodies, was to be held in London next year.

PART-TIME NURSING

CONFERENCE AT CHELTENHAM

BY using part-time nurses Gloucestershire has solved the staffing difficulties of its institutions for the old and ailing[1]; and on Feb. 18 and 19 a conference, arranged jointly by the county council and the Ministries of Health and Labour, was held at Cheltenham to discuss the scheme and demonstrate it in action.

At the opening session on Feb. 18, with Lieut.-Colonel JOHN GODMAN presiding, Sir ARTHUR RUCKER (Ministry of Health) spoke of the great and growing scarcity of nursing and domestic staff which is likely to endanger the working of the National Health Service. This service is suspected in some quarters of all the dangers of bureaucracy; but part-time nursing should help to counteract this danger by stimulating local interest in the care of the sick and the old. The Ministry of Health have sent to the regions suggestions for part-time schemes, some of which have already been started. A part-time scheme for London was launched on Feb. 15.

Mr. A. F. ROUSE (Ministry of Labour) mentioned over 30,000 nursing vacancies notified to his Ministry, and he thought there might be 15,000 others. The war, he said, could hardly have been won so soon without the help of part-time women workers. The Gloucestershire County Council have handled their people well, with full regard to their family commitments.

VIEWS OF THE ORGANISER

Mr. WILLIAM SHEE (public-assistance officer, Gloucestershire) said that he launched the scheme on Jan. 29, 1946, as a last resource. At that time the county services were about to break down. In less than a year the whole picture had changed; not a ward has had to be closed, and the hospitals for the chronic sick are now fully staffed. The Civil Nursing Reserve, who during the war should have saved the situation for the country at large, were lost to nursing by the dozen, he said, because they were regarded as supernumeraries. Part-time workers must be regarded as "staff," and given full responsibility while they are on duty, even if they only come in for a few hours a week. Part-time nursing staff includes regulars, reserves, and casuals, the last being particularly useful at the weekends, when they are often willing to relieve full-time staff. They are classified, according to their experience, as trained nurses, enrolled assistant nurses, nursing attendants (with some previous nursing experience), and nursing orderlies (with no previous nursing experience). They are all engaged in nursing duties, and do no domestic work.

Pay scales had to be worked out. The National Joint Council has fixed rates for domestic workers at 1s. 4d. an hour for cleaners, 1s. 5d. for housemaids, and 1s. 5½d. for ward orderlies doing domestic work. It seemed common sense, Mr. Shee said, that a woman doing nursing should not be paid less than a cleaner; the rate for nursing orderlies was therefore fixed at 1s. 6d.

Attendants were offered 1s. 9d., and trained nurses 2s. 6d.—an average based on the Rushcliffe rates, which range from 2s. 0½d. to 3s. Enrolled assistant nurses were offered 2s. The latest Rushcliffe scales for part-time nurses offer 2s. 10d. to sisters, only 2s. 1d. to trained staff nurses, 2s. to enrolled assistant nurses, and only 1s. 5d. to "intermediate assistant nurses."

This last figure, in Mr. Shee's opinion, may be right for women who can complete their training and become enrolled; but part-time workers have not this opportunity.

The Gloucestershire workers are collected from approved centres and sent in taxis to their work. Seven of the nine county hospitals for the chronic sick are in isolated country places, and the workers travel 7200 miles a week, at a cost of £10,000 a year, or 5s. per bed per week. They are allowed travelling time from the centre and a meal on duty; if they want it, they can buy another meal at canteen prices when they come off duty. The full-time staff, thanks to the newcomers, now do a straight 8-hour span of duty daily, instead of a 13-hour span with some hours off; since they, too, are now given their meals in duty time, their weekly hours of work are actually below 48—about 42, in fact. Uniforms of pleasant style are provided and laundered for part-time workers. After six months' service they get holidays with pay; if it happens that a husband's holiday falls due before the six months is up, the worker is allowed to take hers at the same time, but must come back and complete her six months before she receives her holiday pay.

---

[1] See *Lancet*, 1946, ii, 873.

The council has advertised in the press, and by posters and cinema slides, and by addresses to women's organisations; but the best advertisement has come from the women who do the work. A fine type has been attracted from the start; of the 301 engaged, 72 are trained nurses, 32 enrolled assistant nurses, 92 nursing attendants, and 105 nursing orderlies. Only 4 had to be refused as unsuitable, and only 31 left during the first year; 10 of these left during the first month, but between the sixth and the twelfth month only 6 left. Some 86% are married, their husbands' occupations ranging from unskilled or skilled labouring to professional work.

The cost of a 66% part-time service, Mr. Shee reckons, is no greater than the cost of a whole-time nursing service, supposing you could get it; for much must be spent on up-to-date nurses' homes, and large sums go on expensive labour engaged from nurses' coöperative agencies. It seems that a hitherto unused source of labour is being tapped. When a hospital in a neighbouring county lost its entire staff, the Gloucestershire County Council were able to staff it completely at 36 hours' notice, from among their reserve part-time workers. There is no age-limit for candidates, and the average age of those recruited is 38½. Most of them have children, with an average of 1·8 children per worker. The shifts run from 8 A.M. to 12 NOON, NOON to 4 P.M., 4 P.M. to 8 P.M., or (on night duty) from 8 P.M. to 8 A.M. The patients are left to sleep until 7 A.M., and are washed by the day staff.

Some 56% of part-time workers have had previous nursing experience, and the inexperienced are taught at the bedside by the trained staff. Nursing orderlies in due course gain promotion to the grade of nursing attendant. While believing that the State-registered nurse should have a high standard of training, Mr. Shee feels that the aim of such a standard must always be the good of the community, not merely the status of the nurse: training standards should never be allowed to create hardship for the sick. The success of the Gloucestershire scheme has been due, he considers, to the interest and coöperation of the matrons; and it is important to cultivate the right orientation of mind in matrons who are to work such schemes. He holds that no hospital should now close a ward unless everyone concerned is satisfied there is nothing for it but defeat.

EFFECTS OF THE SYSTEM

Dr. H. **KENNETH COWAN** (M.O.H. for Gloucestershire) finds that patients like the part-time system, not only because it provides enough nurses to look after them properly but because they enjoy news from outside the hospital, and the sight of fresh faces. He suggested that part-time nursing will have a permanent value in the care of the chronic sick, and may well apply in sanatoria, and possibly in acute general and special hospitals, where part-time workers could be used to supplement full-time staff.

Mrs. B. A. **BENNETT** (Ministry of Labour) told how her critical nurse's eye had been satisfied on a tour of the Gloucestershire infirmaries. She saw there, she said, well-nursed patients, happy nurses, splendid bedside teaching—in fact, the loving care of old people. Mrs. F. W. **REYNOLDS** (matron of Cheltenham County Infirmary) remarked that she now has a staff waiting-list. The part-time nurses are treated, and work, as part of the team. On public holidays they have volunteered to relieve the full-time staff by making up rotas among themselves.

On Feb. 19 Dr. B. H. **HASLETT** (consulting physician to the county infirmaries) described the types of patients nursed. Most of them are over 70, many are senile, some have rheumatic disorders, others need reablement after a stroke, a few are late cancer cases, some are incontinent. It is slightly demoralising work, he said, to change the same incontinent patient several times a day; but a part-time nurse usually has to do this only once in her span of duty, and may therefore suit the patient better than the full-time nurse. It is important to get patients out of bed if they are well enough, and to dress them in their own clothes. This means more work for nurses, and may be neglected where staff is scarce. In 1945 in some of the infirmaries the matron was the only trained nurse on duty, and it was becoming necessary to reduce and simplify treatment, especially surgical treatment, instead of expanding it. Now it has become possible to undertake more surgery in the infirmaries and even to reduce the waiting-list in the general hospitals by using spare infirmary beds for people needing urgent operations. He considers that each large ward should have a full-time sister, if possible, though in emergency part-time workers alone can run a small hospital. The women attracted, being more mature and experienced than most recruits to nursing training, are also more considerate to the old. If acute and chronic patients could share the same hospitals, nurses in training would get experience of both, and some would choose to specialise in the care of the chronic sick. It is true that part-time workers usually have divided loyalties, and may have to give up work for a time to meet demands at home, but this must be accepted and allowed for. They seem to like the work and to want to come back to it; and this is the only system which allows the married trained nurse to carry on with nursing.

In reply to a question, Dr. **COWAN** said that the council hoped to extend the system into maternity hospitals. Miss D. E. **WESTMACOTT** asked whether the danger of introducing infection into maternity wards in this way had been considered. Dr. **COWAN** replied that in wards designed to take 40 they have had as many as 70 patients in labour, while the staff consisted of only 10 midwives instead of the full complement of 18. It is better, he thinks, to have a staff adequately supplemented by picked part-timers than to try to deliver patients with insufficient staff.

OPINIONS AND CONCLUSIONS

Mr. **SHEE** asked whether the meeting would care to consider a resolution criticising the Rushcliffe scales for part-time nurses, but on the assurance of three members of the Rushcliffe Committee that all that had been said would be reported and considered, he did not press the suggestion.

In further discussions, and during the course of a brains trust held on the evening of Feb. 18, the case of the trained nurse who has been away from nursing for many years was raised. A sister who has returned to part-time work after a 13-year interval remarked competently "I took hold of a swot-book and got the new stuff up." Asked whether she felt that, as matron, she could give a part-time nurse the full responsibility of ward administration, Mrs. **REYNOLDS** replied: "Of course. I don't look on them as 'part-time workers'; they are my nurses."

This attitude to part-time workers was emphasised by several Gloucestershire speakers; and it is evident, as Mr. Shee claims, that the hospitals regard themselves as being staffed by part-time workers, supplemented by what full-time nurses are available. Mr. C. A. W. **ROBERTS** (Rushcliffe Committee) pointed out the possible application of part-time nursing to mental hospitals; and Mrs. E. O. **JACKSON** (matron of University College Hospital) considered that it was the answer to the problems of hospitals for the chronic sick and of small hospitals. She thought it might even be applied in some departments of training schools. At the same time she pointed out that the assistant nurse's qualification was established to regularise the position of untrained women in nursing; since part-time nurses cannot at present train for any qualification, the old situation may to some extent be re-created.

Mr. W. E. **LEOPOLD** (Ministry of Labour) emphasised the careful way in which the Gloucestershire scheme was launched—the steady build-up, and the care taken to overcome prejudice before the campaign began. He asked those starting schemes to keep this in mind, yet to remember the urgency of our need; and he begged them to let the Ministry know of their successes and failures. "Where people will not coöperate," he said, "tell us, so that we can back you up."

VISIT TO THE HOSPITALS

A visit to some county infirmaries during the afternoon of Feb. 18 confirmed what had been reported of the scheme. There were ample nurses on duty, doing their work peacefully, at a rate which permitted them to be thorough and careful. All the patients questioned were pleased with their treatment, and those who had been in long enough to see the change-over spoke enthusiastically of the part-time scheme. The standard of comfort was clearly high, and the matrons did not look harassed. The part-time nurses were keen and satisfied, enjoying the rewards of nursing without the fatigues and frustrations sometimes associated with full duty, and bringing to their task freshness and the judgment and initiative which family life fosters. They were on pleasant terms with the full-time staff, who spoke of them appreciatively.

ROYAL COLLEGE OF SURGEONS

HUNTERIAN FESTIVAL

THE Hunterian oration of the Royal College of Surgeons of England was delivered on Feb. 14 by Sir JAMES WALTON, consulting surgeon to the London Hospital, whose subject was Hunterian Ideals Today. It was, he said, by the study of John Hunter's specimens and his series that the importance of his work could be best appreciated. Though his collection had been grievously damaged during the war, much would be gained from the council's decision that, instead of being kept separate as a historical group, the remaining specimens should form a living centre of growth in each section of the museum.

At the Hunterian dinner held in the college that evening, H.R.H. the Duke of GLOUCESTER, himself an honorary fellow, reported that in Australia he had fulfilled the council's commission to bestow the honorary fellowship on Sir Hugh Devine. The PRIME MINISTER, speaking of the National Health Service Act, said that in his experience very few Acts of Parliament came up to the hopes of their authors, but still fewer fulfilled the fears of their opponents. The main object of this Act was to make available to all the benefits formerly confined to a few. The acceptance of this "very great aim" marked a big revolution in ideas—a revolution due not only to politicians but also to doctors. "I am quite sure," added Mr. Attlee, "that as we are united in aim we shall in our British common-sense way find a method by which we can all work together." Sir ALFRED WEBB-JOHNSON, the president, said that the profession was deeply conscious of its responsibility. No health service could be a success without its cordial coöperation, and if flaws were found in the plan he had sufficient confidence in the common sense of the British people and of Parliament to feel sure that those flaws would be removed. Turning to domestic affairs, he mentioned that £144,000 has now been subscribed towards the £250,000 needed for restoration of the college. At present 200 graduates are attending classes, and the London colleges are still foci on which men from other countries concentrate.

Sir HENEAGE OGILVIE's toast of the Guests drew replies from the Lord CHANCELLOR (Viscount Jowitt) and Prof. LOUIS BAZY, past president of the Académie de Chirurgie de Paris, who had just been admitted an honorary fellow. Speaking of the proposed treaty of alliance between France and Britain, Professor Bazy said that it was already signed in the hearts of all Frenchmen. Sir CECIL WAKELEY proposed The Hunterian Orator, and in an eloquent reply Sir JAMES WALTON pleaded for a return of kindliness, courtesy, honesty, and charity—between men and between nations.

Those present included the SOVIET AMBASSADOR, the Earl of ATHLONE, Viscount ADDISON, K.G., F.R.C.S., and Mr. ANEURIN BEVAN.

GENERAL MEDICAL COUNCIL

SESSION FOR PENAL CASES, FEB. 25

AT an extra session, held on Feb. 25, Mr. John James Robertson, M.P., introduced by Dr. R. W. Craig, joined the council as a Crown nominee for five years. Three penal cases were considered.

Alexander Lawrie, registered as of 113, Manchester Road, Accrington, Lancs, M.B. Edin. (1932), had been twice convicted in 1944 of being drunk in charge of a motor-car; in February, 1945, the council had postponed judgment for two years. Being satisfied with his conduct in the interval, it now decided not to erase his name.

Christopher Whitehead, registered as of 62, Hockley Hill, Birmingham, L.R.C.P.I. (1926), had been convicted of drunkenness in charge of a motor-car in May, 1944. In February, 1945, judgment was postponed for two years. In April, 1946, he was convicted again of being drunk in an omnibus. He was summoned to appear before the council in November of that year, but was prevented by illness from attending. He now appeared accompanied by Mr. G. E. Evans, of counsel, instructed by Messrs. Donald, Darlington, and Nice. The President (Sir Herbert Eason) reminded him that he had been warned at his last appearance that if he should be convicted again during his period of probation the council might forthwith direct the erasure of his name.

Mr. Evans said that the respondent's conduct had been unblemished before the convictions. He deeply regretted his recent lapse. To relieve an attack of giddiness he had taken three double whiskies at 11 A.M. After his conviction he had entered a hospital and had been discharged on June 1, having responded well to physical and psychological treatment. The medical superintendent reported that his blood-sugar balance was unstable and that he was accordingly highly sensitive to alcohol when fasting. Now that he understood the cause of his trouble he promised to abstain in future. He had arranged to purchase a practice, and to see the vendor on the next day. He produced several testimonials to his professional excellence.

Dr. Whitehead gave evidence on his own behalf and said that he had been practically a total abstainer since his conviction, and had not been on duty at the time he had been drunk. The council postponed judgment again until February, 1949.

Donald Gordon Coutts, registered as of 23, Jordangate, Macclesfield, Cheshire, L.R.C.P.E. (1923), had been sentenced to three years' penal servitude in September, 1946, for the theft of a pound note from a hotel bedroom and of a number of toilet articles the property of a hotel landlord; he had pleaded guilty and admitted 28 other offences. He had previously been cashiered from the Army for cashing several worthless cheques in India and for remaining absent without leave for a month. He did not appear in answer to his notice, but wrote to the council saying that he was in prison and could not afford the expense of the journey. Mr. F. P. Winterbotham said that the Lord Chief Justice, in dismissing his appeal against sentence, had said that he had been a satisfactory doctor but this had given him the less reason for plunging into crime; he had preyed on hotel-keepers for seven or eight months, and it was useless to say that his nerves were wrong. Mr. Winterbotham read a statement from Dr. Coutts, and other evidence, tending to show that he had been treated over several years for severe psychoneurosis. The council found the charges proved and ordered the erasure of his name.

The council considered in private its draft recommendations for the medical curriculum, and the report of a committee which held conferences with the medical defence societies and the British Medical Association on penal procedure under the council's draft Medical Bill.

"... the main differences between the good doctor and the bad are history-taking and planning. Both need time. The good doctor takes a careful history, which is the most important part of his examination. He does not leave the case until he has a plan of action. He may not have made a diagnosis, but he has made a decision. The bad doctor has made neither. Without a decision, reassurance and explanation are impossible."—Prof. ROBERT PLATT, addressing the north-western branch of the Society of Medical Officers of Health (*Publ. Hlth, Lond.*, February, 1947, p. 99).

In England Now

A Running Commentary by Peripatetic Correspondents

A LIGHT flurry of new snowflakes has filled the animals' footmarks, which are now picked out in white on the grey sheet covering our fields. Why snow should go grey down here in the country was a mystery to me till I realised that all this dirt is just a ten days' deposit from the cloud of smoke that always hangs over England.

Much preferring the traditional coal fire to anything that comes out of a wire or a pipe, I've always looked askance at the activities of the National Smoke Abatement Society; but I was shaken last autumn by their Sir George Elliston's remark that 10,000 of our miners spend all their days in producing the smoke that interrupts our sunshine. Almost more disturbing was Mr. E. Minshall in the *Manchester Guardian* of Feb. 17, who showed that burning raw coal is about as wasteful as buying milk and pouring away the cream. It seems that 1,000,000 tons of this stuff, treated scientifically, will yield 390,000,000 cubic yards of coal-gas (which I calculate would grill 97,500,000 underdone fillet steaks), 420,000 gallons of motor fuel, 250 tons of phenol, 1000 tons of cresol, 4000 tons of naphthaline (which would at last drive the carrot-fly right out of our garden), 22,000 tons of pitch, 800,000 gallons of Diesel oil, and 640,000 tons of coke (of which 2 cwt. was, thank goodness, delivered to us last week).

> "When it is considered," said Mr. Minshall, "what proportion of coal mined is burnt without any regard to the collection of these raw materials it is at once realised that the people are sacrificing untold wealth in order that they may enjoy the doubtful privilege of a very inefficient mode of heating and that industry should enjoy the obnoxious privilege of dispatching into the atmosphere each year many thousands of tons of soot, tar, acid vapours (sulphur dioxide and hydrochloric acid), and other substances injurious to public health."

Regardless of the public health I shall continue to defend the burning of coal in the domestic grate—as a deliberate luxury. But hasn't the time come when stokers at our power-stations and throughout industry might be denied this atavistic pleasure?

Excuse me while I cut up some wood.

* * *

One vivid memory of my schooldays is the joyous abandon with which we at Dulwich welcomed a real good epidemic of German measles in 1895 or thereabouts. I can still recall our delight at feeling the enlarged glands under our ears, and the hectic holiday in the "san." with twenty other high-spirited young devils—three weeks with no more hardship than a dose of purgative; if you were lucky only the gentle and refreshing Eno's. So it comes as a shock to find there is a viper in the bunch of bananas.

* * *

Dressed warmly in our ordinary clothes, despite the presence of a Royal Duke, we were all very comfortable at the Hunterian dinner. Surgeons, said the President, are naturally on familiar ground when it comes to making drastic cuts, maintaining gas pressure, avoiding inflation, and keeping open arterial channels and channels of evacuation. Even Mr. Attlee, displaying the detachment expected of our Prime Ministers at moments of peril, seemed less anxious about the industrial crisis than about the possibility that his hosts, if annoyed by the Health Act, might put him in their famous museum. It remained for the Hunterian Orator, replying to what its proposer called the real toast of the evening, to touch at the last moment on the fundamentals of our national situation. It had always seemed to him, he said, that the best means of attaining happiness is to be occupied with work: "Has anyone ever known a really busy man who was unhappy?" People should not, as now, be laying themselves out to obtain more leisure, but should be seeking absorbing occupation, both for their working years and afterwards.

But Sir James Walton would have to admit that, since the Industrial Revolution, the face worn by Honest Labour has often been deplorably dull; and most people can't begin their "absorbing occupation" till they've secured their leisure. Moreover it isn't always dogs or football: nobody should under-estimate the proportion of its free time which the British public devotes to mildly productive activities such as the upkeep of homes, gardens, and allotments. I have a friend who (it is true) wastes his own weekend in bicycling and thinking: but one of his thoughts is that, if we had another campaign for more home-grown food, any loss to the nation through working a 40-hour week could be largely offset by the value of the vegetables grown in busy hours of idleness at home. Sir James (and anyone fond of vegetables) would like that.

* * *

Shivering in the consulting-room for two hours morning and afternoon may be a change from home, where the water main has frozen again, but the prospect doesn't attract other people, and the consequent dearth of patients would be a source of grave anxiety if one's colleagues weren't in the same boat (or on the same ice-floe). "No-one to see me this afternoon," says the E.N.T. man. "Ditto," says the ophthalmologist, while the gynæcologist complains that his patients, having braved the rigours of the Arctic to get to him, resolutely refuse to prepare themselves for his examination, so the visit degenerates into a social call, or an abortive attempt to break the ice.

Meanwhile one listens to the weather reports over the restricted broadcasting service, in the vain hope of a gleam breaking through; one goes home early to fill the coal bucket from the pathetic little dump in the garden, de-snowing it as best one may; one sends for chilblain ointment (samples), sweeps the snow from the garage approach, fails to buy an ounce of paraffin or anti-freeze, swaps burst-pipe yarns (the modern equivalent of blitz stories) with neighbours, wonders what the next Spens committee will produce, sympathises with the builder's labourer who says if he had money he'd follow the sun, and decides tomorrow to stay a little longer at the hospital to cadge a hot bath in the residents' college. Finally, when one's digital circulation has packed up and one is frozen almost into aphasia, one wonders whether that whole-time salaried job would not have cut a little more ice after all.

* * *

Notorious money-grubbers, we G.P.S. The other day I went 12 miles, got my car stuck, and walked across three ice-covered fields in an east wind to see an octogenarian (N.H.I.) patient whose sole complaint was that he felt cold.

* * *

Leaning back in the comfort of what was once a first-class carriage on our suburban line I opened my *Lancet* of Feb. 8, and idly turning to page 231 seemed to read as follows:

> "Learning physiology as a second-year medical student has its tragic side in our college. I have never understood what pH stands for, and having a brain-wave the other day thought it might be a ferment and asked him who is supposed to teach me whether it was. The poor fellow tumbled against the bench, and burst out into a spate of words that told me nothing. However I led him to think he had made it clear to me, and thanked him. Some days later he introduced another of those combinations of letters in connexion with the blood. This time Rh. . . . He asked me if I understood it and I had to say it came next but one to pH, and was going on to ask why the capital letter had been inserted when . . ."

The train stopped with a jerk at our local terminus and I saved my specs, threw my *Lancet* in my case, and ran up the ramp to miss the bus that is timed just not to meet the train. When I had regained my breath I began to have sympathy for this poor boy. Having a form-visual brain and a sound-hearing mind, I have always had great difficulty in grasping the physiologist's airy somethings without a local habitation. It is not so bad when they have a name—I can at least struggle with a dictionary or a lexicon—but when they are represented by letters that are not even algebraic symbols I am stumped. I believe the Rh factor has something to do with a monkey, though why it should carry a capital "R" while the lion and the lizard keep to a small "l" they do not tell me; but pH is quite meaningless and must remain so till English is no longer English.

Letters to the Editor

THE NATION'S FOOD

SIR,—Mr. Strachey's unsatisfactory answer to Mr. Reid in the House of Commons on Feb. 6 deserves further attention.

> "I believe," said Mr. Reid, "that this nation has now to face greater trials, possibly, than it has ever had to face in its history . . . and unless the diet of this country can be improved, and improved quickly, there is the greatest risk that this country will not pull through the trials which face it in the immediate future. . . . Let us not blink the fact that there is a widespread feeling at the moment that this country has not got the food from outside sources of supply which it ought to have got. . . . We have got to get the materials somehow, and if, by reason of ideological considerations, he [the Minister of Food] refrains from returning to ordinary means of buying and thereby loses food for the people of this country, he and his Government are incurring a very heavy liability indeed, and a very heavy responsibility."

In reply, the Minister said that the country as a whole *was consuming about 7% less food than before the war.* The upper third of the community had found their diet reduced by much more than 7%; the middle third consumed about the same; and the poorest third was consuming far more than before the war.

It is true that there was some improvement in the *national dietary* during the war: the free issue of meals and milk in the schools has done much to benefit the children's health, and everyone is full of praise for the way in which the food situation was handled in the war years. But can the Minister possibly be right in thinking that the middle third consumes about the same, and the poorest third far more, than before the war? This would mean that the reduction in consumption by the upper third was sufficient not only to offset the increase in consumption of the poorest third but also to reduce the country's total consumption by 7%. Either the Minister is wrong in his analysis, or the "upper classes" must have been engaged before the war in almost continuous assimilation.

As members of the medical profession we are favourably placed for hearing the comments of our patients. Is not the story always the same—workmen complaining that they can't do a morning's work on a breakfast of tea, bread, and margarine; housewives at their wits' (and points') end, and going without themselves, in order to find solid food or even sandwich filling for the men-folk; and school-children raiding the larder and devouring the "mousetrap" ration as a snack? The women's wish is always the same—for meat, bacon, butter, palatable cheese, and eggs. Workers on the land, in the factories, mines, and shipyards all tell of the same dearth.

The Government in defence invariably pin their faith to calories. Would that this unfortunate thermic unit had never been invented, for it takes no account of the hosts of other factors, only some of which are understood, which go towards the satisfying and appetising dietary which is necessary for full physical and mental health.

Our national salvation depends on increased production, which so *far is not forthcoming.* If, as Mr. Strachey implies, the workmen are now better fed than before the war, then the outlook for industrial recovery is poor; if, however, as some of us feel, the men and their wives are hampered by food-rationing, now more severe and irksome than in the darkest days of the war, then everything is to be gained by improving the food situation. This is not as impossible as the Government suppose, especially if they heed Mr. Reid's suggestions. The importation of food and feeding-stuffs could be considerably increased at the expense of tobacco, films, and cosmetics. Dutch cheese could be imported more to our advantage than Dutch bulbs.

The American loan was largely approved by the Americans, despite mistrust of our post-war Government's policy, because it was felt that our people were in need of food and machinery; but what can the Americans think of a country whose Government do not avail themselves of the opportunity? Admittedly dollar resources must be carefully nursed, and imports must in part be chosen in relation to exports. Nor are we the only, or by any means the most, ill-nourished nation; but, excepting Germany, we have been engaged longer than any.

The British workman is still a proud craftsman, and if he is properly fed, and can see his wife, children, and parents properly fed, he will not fail to work all out. If well nourished we could again lead and point the way to European recovery; but at present our people have little to work for.

The time has come when the leaders of the profession should, in the nation's interest, review the food situation and assess the present state of our subnutrition, so offering speedy advice to our harassed and maybe well-meaning but insufficiently experienced Government.

Malvern. ROBINA McMENEMEY.

TREATMENT OF TUBERCULOSIS

SIR,—*It is regrettable that a report by Dr. Corrigan and myself* (Dec. 14) on a small group of patients with pulmonary tuberculosis who were benefited by minimal doses of amphetamine should have evoked from at least one correspondent a denunciation of modern methods of treatment. One cannot attempt seriously to reason with Dr. Brailsford when he suggests (Dec. 28) that the lethal condition of phthisis should remain undiagnosed and untreated because he sometimes sees healed lesions in X-ray films. On the other hand, we do not dispute Dr. Simmonds's contention (Jan. 11) that many patients have a very proper faith in surgical treatment, although some are not as phlegmatic as others. Dr. Clive's axe has, we think, been slightly twisted in his hand. We believe that he did not intend his blow to be struck against the use of collapse therapy, but in defence of the fundamental principles of sanatorium treatment (Jan. 25). Surely both are indispensable; but it has become apparent that the active and passive phases of treatment cannot be happily synchronised.

We thought we had made it clear in our article that we used amphetamine only in exceptional circumstances, in order to alleviate undue mental distress. We suggested, moreover, that the drug might have a value not only in the treatment of difficult cases of phthisis but also in general surgery. *It is interesting to recall that a good* deal of disapproval was expressed when anæsthetics were introduced for the alleviation of the physical pain of surgical operations.

Harefield County Hospital, Middlesex. L. E. HOUGHTON.

GERMANY

SIR,—As one who has been in contact with German medicine for about a year, I fully endorse the pleas of Flight-Lieutenant Saunders and Flying Officer Levy (Feb. 8). The inadequacy of medical supplies is serious: paper bandages are still being used even in the larger and better-equipped hospitals.

Penicillin became generally available for the first time in Schleswig-Holstein (and, I believe, the British zone) last October, when, through the agency of the British Red Cross and COBSRA, penicillin banks were established. One such bank was at the Save the Children Fund Hospital, Lübeck. Unfortunately the limited supply *soon ran low.* We have been reluctantly forced to confine the use of the remainder to children until such time as supplies are replenished. So far the situation remains unrelieved.

The employment of penicillin was heartening, and the appreciation of patient and doctor quite inestimable. A group of relief workers in Brunswick, whose salaries are but nominal, sent a relatively considerable sum to London for the purchase of further supplies. It was disheartening and acutely embarrassing to refuse treatment with the excuse that no penicillin was available, while supplies were lying idle, in Military Government stores, waiting for venereal cases.

I would make two suggestions: (1) that the Control Commission should be urged to change the ruling that penicillin be used for *cases of V.D. only*; and (2) that, in view of the low price of penicillin, immediate financial support be given to such organisations as the British Red Cross and the Save the Children Fund for the purchase of penicillin. In these ways we should be counteracting the present deterioration in British prestige and implementing the principles about which the Germans have heard so much.

Save the Children Fund Hospital, Lübeck. DAVID MORRIS.

SIR,—I entirely support the appeal of the two R.A.F. medical officers for penicillin for the Germans. It is utterly humiliating to watch a man die for lack of it, as I have done, while knowing that it is being used for face-cream at home and in America. Helpful though the contribution of the Ecumenical Refugee Commission will be it can only touch the fringe of the problem. The solution is:

(1) To allocate penicillin from British and American production for urgent German needs (which can easily be assessed, if this has not already been done) *before* allowing it to be used at home for trivial complaints. (2) To produce penicillin in Germany.

Nearly two years after the end of the war the huge majority of hospitals in the British zone of Germany have received no penicillin and German doctors have not been trained in its use. I am told that factories in Göttingen and Berlin have been, or will be, started—though I wonder whether two factories will be enough. The resources necessary, unlike those required for other industrial activities, are trifling; the results would be, as they have been in England, tremendous.

This is a matter of public morality, in which we are, therefore, all involved. It is the duty of the profession to insist on the necessary action.

B.A.O.R. DAVID PYKE.

⁂ A statement on penicillin by the Minister in charge of the British zone is reported on p. 309.—ED. L.

THYROID AND COLD SENSITIVITY

SIR,—I have observed—it is but a rough clinical impression—that patients taking thyroid gland for a variety of conditions, both rationally and empirically, have not noticed the extreme cold of recent weeks to the same extent as the majority. This is certainly true of patients suffering from thyrotoxicosis, and of course is as well recognised as is the hypersensitivity to cold of hypothyroid patients.

The thyroid gland of rabbits undergoes hyperplasia within half an hour of exposure to cold; and normal mice given thyroid gland stand exposure to cold without loss of temperature to the degree shown by control mice.[1] This is apparently due not only to the raising of metabolism but to induced greater activity. Whether or not this has any large-scale applicability to normally healthy man is debatable, and raises the question of the significance of reported ill effects of large doses over long periods. Nevertheless, it might be worth investigating the effect of controlled moderate dosage over short periods in groups of healthy volunteers. Certainly, inadequately compensated exposure to cold appears to lower resistance to respiratory infection, apart from its more obvious irksomeness. On the other hand, if we raise metabolism and appetite without being able to provide enough food our final state may be worse than the first.

London, W.1. S. L. SIMPSON.

WHAT CONSTITUTES LIVE BIRTH ?

SIR,—May I be permitted to comment on the article under this title in your issue of Jan. 18, in so far as it affects the provisions of the Births and Deaths Registration Acts?

These Acts prescribe that the birth of every child born alive shall be registered; and in the absence of a legal definition of live birth no arbitrary dividing line has been drawn in relation to duration of pregnancy as has been done in the case of stillbirths.

Accordingly successive Registrars-General have taken the view that it is a statutory requirement resting upon birth informants to register as live-born any child which after being completely expelled from its mother breathed or showed any other signs of life, regardless of the period of pregnancy. The question of viability or non-viability does not affect the requirements of registration. On this interpretation the only births which are not registrable either as a live birth or a stillbirth are the births of children which issue forth from the mother before the completion of 28 weeks of pregnancy, but which in other respects fall within the statutory definition of "stillbirths."

General Register Office, Somerset House,
London, W.C.2. J. M. ROSS.

HEALTH CENTRES OF TOMORROW

SIR,—May I offer my whole-hearted congratulations on the series of articles on Health Centres of Tomorrow, concluded in your issue of Feb. 8? You have given us a complete review of the whole problem and have succeeded in resolving many of the points of controversy that at present divide us.

One of your most important proposals is that there should be two main varieties of health centre: (1) an ideal type, to be put up on a limited scale in relation to a teaching school or some research organisation; and (2) a more utilitarian variety which could be universally applied to the whole country without undue delay. Clearly, the first type would be experimental and would give a valuable guide for the future, while the second type, though based upon the plans for the first, would only contain those elements which were immediately practicable.

Within the scope of this definition, the problem of X-ray apparatus at the health centre is immediately soluble. The ideal health centre would naturally have an X-ray plant; its more utilitarian brother could only hope to have one when we have produced "standardised and simplified apparatus which will not be costly." Meanwhile arrangements should be made for practitioners to have their patients X-rayed at a central department from which films would be forwarded.

Dr. Hoffstaedt's suggestion (Jan. 18) that miniature mass-radiography units should be available for X-raying general practitioners' cases deserves further consideration. Many of us who are interested in the problem of pulmonary tuberculosis have been wondering for some time whether it might not be possible to put this apparatus to a better use. Dr. Hoffstaedt's brilliant solution could go a long way towards solving the immediate problem of chest radiology for patients under the care of a general practitioner.

The question of having a clinical laboratory has also proved to be controversial. I cannot agree with Dr. Stark Murray (Jan. 18) when he opposes such an arrangement. The methods of routine clinical observation have gone beyond the stages of palpation and auscultation to include blood-counts, full urine examinations, and radiography of the chest. Any qualified doctor can do the blood and urine examinations himself, so why not let a group of ten doctors share a small laboratory with a centrifuge? We should not let lack of technicians prevent us from having a clinical laboratory in *every* health centre. It will not be of much value to bring doctors together in a health centre if the old isolated methods of work are to persist. The opportunity for sharing facilities inaccessible to the individual but feasible for the group is the main justification for health centres at the present time.

I believe that your articles may well become the point of departure for plans under the National Health Service Act, and I hope they will be carefully studied. Would it be possible to reprint the series, and the leader of Jan. 4, as a small booklet, and to send a copy to every general practitioner?

Grove Park Hospital, London, S.E.12. P. W. ROE.

SIR,—The ideal which inspired your excellent articles on the health centre is to secure the best possible service for every patient; and I reply to the letter of Dr. H. B. Porteous (Feb. 1) only because that ideal cannot be reached unless every detail is fully discussed. The difference between us is, however, entirely one of words. My use of the words "central laboratory" appears to have given him the idea of a great institution serving a very large unit of population, and of practitioners waiting days for a result. I agree that such a service would be entirely wrong. What I want to see is a central laboratory that provides every general practitioner within the normal health-centre unit with the most rapid and complete service that can be given.

---

[1] Tanner, M. L. *Endocrinology*, 1946, 38, 263.

May I give an example from my own laboratory? Contrary to the ideas of most people, I spend a large proportion of my time in consultation with general practitioners either in the laboratory or in the homes of their patients. A few days ago—and this is the everyday routine of this laboratory—I was asked to see a patient whom the general practitioner thought might be suffering from agranulocytosis. The patient lived eight miles from the laboratory, which is the extreme limit of the radius we cover; nevertheless he was visited, swabs of the throat were taken, blood-counts were made, and the general practitioner was discussing the result and the best method of treatment in less than three hours.

Dr. Porteous repeats the assertion to which I took exception in your original article—namely, that "if five doctors were working as a group and using regularly the ordinary routine laboratory tests they could fully employ one technician." What I asked for, and have been seeking for years but have never been able to find, are actual figures to substantiate this assertion. Until they are produced I shall still believe that the best clinical pathological service is one in which *the pathologists are mobile*; the laboratory should serve a unit of *population not exceeding 100,000, and should be capable* of carrying out the whole of clinical bacteriology, hæmatology, and other associated sciences, at the request of *the family doctor and in the closest contact with him* and his patients.

Richmond, Surrey. D. STARK MURRAY.

DOSAGE OF NEPENTHE

SIR,—In your recent report (Jan. 25) of a death following an excessive dose of this drug you say that "nepenthe is a proprietary preparation of opium, containing about gr. 1 in 130 minims." Surely this should read: "Nepenthe is a proprietary preparation of opium, containing about gr. 1 of anhydrous morphine in 130 minims."

London, S.W.1 GEORGE E. SPEAR.

*** We are glad to have this error corrected. 'Nepenthe' *contains 0·84 % of anhydrous morphine.*—ED. L.

WOMEN DOCTORS AND SERVICE SPECIALIST APPOINTMENTS

SIR,—The Medical Women's Federation has been informed of the extreme difficulty which is being experienced in finding replacements from civilian life for the specialists (men and women) in the Services whose release is behind all other medical personnel—in the Army, for instance, it is 12 groups behind.

There is at present no conscription of women. As many women doctors know, in June, 1945, the Ministry of Labour, by a Cabinet decision, abandoned the call-up of women, and the doctors were included in the general ruling. The Medical Women's Federation wrote a letter at the time to the Ministry of Labour, which was afterwards reported in the medical press, pointing out that this exemption was contrary to the wish of medical women; it deplored the position and said that in professional matters women doctors wished to be treated as doctors, and not to have special privileges as women. Similar representations were made by the Services themselves and by the Central Medical War Committee. The Ministry of Labour, however, was not willing to rescind the order as applying to women doctors, but pointed out that they were at liberty to volunteer.

It must be admitted that recently the Service intake of volunteer women doctors has been very small. This has had the unfortunate consequence of delaying the release of serving specialists, both men and women, and of necessitating the call-up of an unfair proportion of men doctors, many approaching forty, on whom it may inflict serious hardship.

Young women of the graded or full specialist class must realise, furthermore, that their immunity from conscription is certainly not entirely to their advantage. B1 posts and higher hospital appointments are being reserved to a great extent for returning Service doctors or for those who are "recruitable," in order that, in the latter case, there shall be some specialists trained, in due course, to replace those who are now going into the Services.

The Medical Women's Federation wishes to draw the attention of all young women specialists to this urgent need, recognising however that this is only a short-term measure. Long-term policy involves the consideration of the conscription of women doctors equally with men, but this is bound up with the rectification of certain anomalies in the status of medical women serving with the Army and R.A.F. In spite of this, however, the federation urges eligible women specialists to offer their services *now*, chiefly for the sake of those who are being retained unwillingly or called up; and perhaps also for their own sakes, as on leaving the Services they will be in a strong position in applying for further appointments.

MARY F. LUCAS KEENE

Hayes, Kent. *President, Medical Women's Federation.*

NIGHT WORK

SIR,—I wonder whether the advisers of the Government have considered the consequences carefully before recommending night work for millions of people, including a great number of women.

As one who supervised several thousand women during the war years I know that they did magnificent work when their social problems were understood. The single young women were keen on doing night work with its close companionship and the chance of being out in the daytime. They needed little sleep at their age, and food was provided for them. In most cases they also had a certain amount of service because they lived at their parents' homes, or in hostels or lodgings. Incidentally, hospital nurses on night duty fall into this group, and show a very low rate of sick absenteeism; they are also the women on night work who have been observed for the longest period.

The young childless married woman, without a home of her own, and with her husband in the Forces, was in very much the same position except when her husband came on leave. The position of the married woman with obligations was, however, entirely different. Even the childless married woman, whose husband was away had more worries if she had a home of her own and was proud of it. Experience showed that women with young children worked most satisfactorily when they were employed on part-time work only, preferably between 10 A.M. and 5 P.M., provided they had Saturday off to do the week's shopping and the main cleaning.

These problems have increased since the return of the men from the Services. Care of the home and family life are of paramount importance, particularly as both men and women have often had to make a great effort to readjust themselves. Happily, this process of resettlement has usually proved successful, but it must not be endangered again. Physical and mental exhaustion and renewed disturbance of their hard-won married and family life will constitute a real danger. Unless the lessons of the war-years are remembered, and married women are exempt from night work and are given sufficient time off to run their homes, the result may be an increase of absences through sickness and a net loss of woman-power.

MEDICUS.

SUPRASPINATUS SYNDROME

SIR,—I read with interest Mr. Armstrong's article (Jan. 18), and I was pleased to note that Mr. Mayer (Feb. 1) advocates deep X-ray therapy as an alternative to surgery.

I cannot entirely agree with Mr. Armstrong's view that surgery alone will cure a third of the cases which do not cure themselves. Mr. Armstrong has dismissed physiotherapy for the supraspinatus lesion with a wave of the hand, as being useless. Whilst agreeing that radiant heat is a waste of time, long-wave diathermy, with one pad applied over the supraspinatus muscle belly and the other over the acromial bursa, will produce great relief from pain. However, a treatment with even more dramatic effects is the production of three Kromayer burns in the line of the tendon, repeated after some weeks if the first application has not cured. This treatment has cured most of my cases of supraspinatus tendinitis. In my experience, operation on the tendon sheath, with scraping or excising of the calcified area, produces intractable stiffness. With arthritis of the acromioclavicular joint, which I never can cure by any physiotherapy, excision of an inch of the acromion appears a very suitable procedure.

London, W.1. G. O. TIPPETT.

ACUTE PORPHYRIA

SIR,—In connexion with the observations of Dr. Gray and Professor Rimington (Feb. 1) we would remark that the paper by Watson and Schwartz came into our hands only after we had read the proof of our article. We knew then that certain of our views must be considered wrong. We thought it unnecessary, nevertheless, to send a correction, since the main purpose of the article was to draw the attention to the disease and its connexion with the barbiturates.

We still feel that the benzaldehyde test performed on the urine after extraction with ether is a simple and adequate test for porphobilinogen. If this test is negative after the urine has been made alkaline by giving the patient sodium bicarbonate the diagnosis of acute porphyria is wrong. This method of excluding the diagnosis is simple and can be carried out under primitive conditions.

We may further add that we have recently observed a third case of acute porphyria in which the excretion of porphobilinogen in the urine was provoked by the ingestion of barbiturates.

ADRENAL APOPLEXY

SIR,—I was interested in the report by Dr. MacMillan (Feb. 1). But his suggestions as to ætiology raise considerable difficulties.

If the hæmorrhage came from a vessel weakened by hyalinisation, it seems an extraordinary coincidence that the bursting-point was reached at the same time in both adrenals. Severe hyalinisation of adrenal arterioles is a fairly common post-mortem finding in deaths from hypertension, whereas adrenal hæmorrhage must be very rare as a termination of this disease. It seems that the hypertension can have played, if any, only a very small part; and some more important factor must surely have been present. It is hard to guess what that factor may have been; but, despite the initial absence of pyrexia, do the clinical and pathological findings totally eliminate an undiagnosed fulminating septicæmia (perhaps meningococcal)? A blood-culture and examination of the cerebrospinal fluid might have been instructive.

Pathological Department, King's College Hospital, London. G. F. M. HALL.

LESSER CIRCULATION OF THE KIDNEY

SIR,—We feel that some comments are necessary on the communication by Trueta and his co-workers which appeared in your issue of August 17 and on the leading article which appeared in the same issue. The techniques of these workers leave no doubt as to the existence of an anastomotic vessel, probably the Isaacs-Ludwig arteriole, which enables the cortical circulation to be short-circuited. We must say that we are far from happy about the experiments in which dye was used as an indicator of the patency of vessels, and we feel that the results would have carried more weight had some of the precise clearance techniques, advanced by Prof. Homer Smith, been used. This point is of particular significance in view of the remark appearing in the communication "the interpretation of renal function tests must be reconsidered." So long as urine is being formed by the kidney, filtration must be occurring at the glomerulus; and its extent is of importance, for unless this is known diuresis may equally well be explained by exclusion of the tubular circulation.

The theory of Cushny, published in 1917, made it apparent that the factor deciding the extent of filtration at the glomerulus was the blood-pressure and not, as Heidenhain had postulated in 1874, the blood-flow. If the blood-flow through the glomerulus is completely cut off then obviously filtration will cease: but it is impossible to draw any further conclusions from this limiting case, since the maintenance of a normal glomerular filtration rate may be associated with a profound reduction of renal plasma flow and urine volume.[1] While it may be valid to draw conclusions as to the extent of the glomerular filtration from urine flow in the rabbit, the animal presumably used in these experiments, such a correlation has never been demonstrated in other mammals, including man.

In the absence of exact information as to the extent of glomerular filtration and renal blood-flow there appears to be no evidence for the remark in your leader—"during active diuresis, the cortical circulation is fully open, while in anuria the medullary circulation is in action and the cortical circulation is thus bypassed"—if intended to apply to any animal other than the rabbit. From quantitative data,[1] however, it is clear that changes in the cortical circulation are of relatively minor importance in the determination of urine volume in man.

PENICILLIN IN LUNG ABSCESS

SIR,—We were glad to see your annotation of Jan. 11; but, in saying that in pulmonary suppuration "the effects of . . . penicillin were uncertain, possibly because of inadequate trial," it misses what we consider the most important point of our paper.[1] It is our opinion that penicillin is a life-saving drug in acute putrid lung abscess, and re-reading of this paper will, we hope, dispel any doubt. Since it was published last July, we have had many more cases of this disease cured completely and saved from unnecessary and difficult surgery by the simultaneous administration of penicillin and sulphadiazine. The cures have now reached over 90%.

New York. J. KAVEE.

Public Health

Setting the Ball Rolling

ON the passing of the National Health Service Act county and county-borough councils became "local health authorities." Till the appointed day they will have no executive functions, but they will have much to do in preparing for their new rôle. They should begin, the Minister of Health suggests, by setting up a health committee, which should in turn appoint subcommittees to plan the various services. In his circular (22/47) the Minister gives the following as the latest dates for receiving their proposals: June 30, vaccination and immunisation, and ambulance services; August 31, midwifery, health visiting, home nursing, prevention of illness, care and aftercare, domestic help, and duties under Lunacy and Mental Treatment Acts and Mental Deficiency Acts: Sept. 30, care of mothers and young children: Nov. 30, health centres.

The Minister urges that the committee and subcommittees should include an adequate proportion of women, and that coördination with related services should be secured by appointing members from, for example, the education committee and the existing maternity and child-welfare committee. Under the Act an authority is free to go outside its own membership in making appointments to the committee, and this power will allow it to obtain the collaboration of doctors and other experts, and of representatives of such bodies as the local hospital management committee.

The Minister does not intend to initiate action to form joint boards, though where authorities themselves wish to combine he will be prepared to consider making an order accordingly. The advantages of arrangements made jointly—as distinct from joint boards—are, he adds, obvious.

The immediate aim of the authorities should be to provide as efficient and comprehensive a service as possible on April 1, 1948. But it would be neither possible nor desirable for their first proposals to be too cut and dried. Before health centres, for example, can be set up much detailed consultation with the medical, dental, and other professions will be needed. The proposals to be submitted by Nov. 30 could, the Minister suggests, suitably deal with such topics as the reservation of sites, especially on housing estates.

No case of cholera, plague, or typhus was notified.

In the 2 cases of smallpox at Grimsby illness began on Feb. 13–14; both patients, who have since died, were unvaccinated. There were 10 further cases up to March 4, with 2 more deaths. Infection, the source of which is unknown, occurred in a lodging-house used by seamen and farm labourers. Of the contacts there 10 cannot be identified, having moved on either by land or sea—most probably on trawlers or coastal vessels.

The case of relapsing fever was notified at Haltemprice, East Yorks.

Parliament

ON THE FLOOR OF THE HOUSE

PARLIAMENT last week grew heated over fuel, heard Mr. Ernest Bevin's reasons for referring the Palestine question to the United Nations, and discussed foreign affairs in the light of the forthcoming conference in Moscow. On the whole, the international prospect lightens. The Anglo-French treaty, now being signed, has an importance not yet fully appreciated. We approach the time when the peace treaties—all of them—will be made, and when nations can disagree about details without feeling that the fabric of international understanding is in jeopardy. The difficulties in Germany are very great indeed; but we are seeing such difficulties more vividly and more clearly now because there begins to be a light in the sky, which more and more of us believe will break into the full sunlight of agreement between the nations. If the United Nations can give the world peace and stability at the centre of its affairs, this peace and stability will be reflected in the individual countries.

British policy must be framed so as to allow for two alternatives: (1) that the United Nations comes into being strong, supported by a great majority of all peoples and armed with an international police force central organisation will be less strong, leaving each capable of making its authority respected; or (2) that the nation to depend on its own navy, army, and air force. Like the U.S.A., the U.S.S.R., and every other country, we are having to budget politically for both of these alternatives. But the world is tired of navies, armies, and air forces, and it is very improbable that it can continue to employ so much scientific research power, so much organising power, and so much plain honest-to-goodness man-power for military purposes, and yet remain solvent and reasonably comfortable—let alone guarantee to all men freedom and the pursuit of happiness.

As part of this lesser policy of self-defence there will soon be coming before the House a National Service Bill which will define the conditions of service in the Armed Forces which will be laid on all of us in Britain at an early date. This will certainly impose a strain on the medical profession, which by then will be carrying the responsibilities of the National Health Service. How far medical service in the Armed Forces and medical service in the N.H.S. can run together still remains to be worked out in detail. But if we become involved in a future war the civil and the Service sides of the medical profession will certainly have to be more intimately coördinated than during the recent one, and perhaps their members will be interchangeable This would only be carrying the idea of the E.M.S. organisation of the civil medical profession in the late war a stage further.

The medical group in the House of Commons will very soon be considering its policy on these questions, and a statement of the medical viewpoint will be made in Parliament when the Bill comes up for discussion. Meanwhile the Secretary of State for War has told us that the strength of the Army on Dec. 31, 1946, was 896,757 and that its strength on Dec. 31, 1947, is estimated at 660,000. But, he added, the strength "clearly depends on a number of factors." In other words, is the world going on the road to union in the United Nations or to division in strife between the powers? Each nation has to ask itself, where am I going?

MEDICUS, M.P.

FROM THE PRESS GALLERY

Conditions in Germany

In the House of Commons on Feb. 5 Mr. RICHARD LAW called attention to the appalling gravity of the situation in the British zone in Germany. There 20 to 30 million human beings were rotting to death and we deceived ourselves if we imagined that corruption could go on in Germany and not spread far beyond its confines. If we wanted to save Europe we must call a halt. By our mismanagement and good intentions he believed we were sowing the seeds of a third German war. He had been to the homes of the German people and seen the little children listless and puffy, with no shoes and in a terrible state of health, and from his own experience he knew that the food conditions in Germany had not been exaggerated. Our proper policy now, Mr. Law affirmed, was to abandon all this idea of trying to run the Germans for their good and to revert to the conception of control. We should help the Germans, but leave it to them to organise their industries.

Mr. J. B. HYND, Chancellor of the Duchy of Lancaster, replying for the Government, said that the key criticism of the Government was that they must send more food. They had sent more food and given the Germans more than the 1500 calories ration. This criticism ignored the desperate efforts which the Government had been making for the last eighteen months to get even those quantities of food into Germany. He admitted there had been local breakdowns but overall the ration had been maintained at 80 to 85%, and where it had fallen in one period it had been made up as far as possible later. There was a misunderstanding over the rations. The basic ration for the non-working adults was 1550 calories. But they represented only 30% of the population. The remainder were categorised according to the work they did, and their rations ranged from 2500 to 3000 calories which, in the opinion of the tripartite nutrition committee, was sufficient. In addition, 1,700,000 children in German schools were receiving free meals as well as their ordinary rations. Already the American and British authorities under the fusion agreement had fixed a target of 1800 calories for the normal consumer as a first step. But they recognised that nothing less than 2000 calories could be regarded as approaching a satisfactory condition.

Medical Supplies

On Feb. 6, replying to Mr. A. F. SKEFFINGTON on the question of an increased demand for medical supplies under the National Health Service Act, Mr. C. W. KEY, then parliamentary secretary to the Ministry of Health, said that through the Emergency Hospitals Scheme substantial quantities of medical supplies and apparatus were issued to the hospitals to enlarge the scope of their work. These were additional to the ordinary supplies maintained by the hospitals themselves for their current needs. Arrangements had also been made to acquire surpluses from our own, the Canadian, and the American Forces for the use of our hospitals. The hospitals would not be asked to pay for such supplies, which would remain Government property. In these ways hospital supplies were being gradually built up. Looking forward to the future the Minister had set up expert working parties, with which were associated representatives of the Ministry of Supply and of the Service departments, to assess the requirements of the new health service, beginning with radiological and laboratory apparatus. The working parties would later consider theatre and ward equipment, dental apparatus and ambulances, and the needs of special departments of hospitals, such as ear, nose and throat, and physiotherapy departments. Care would be taken not to go too far in the way of standardisation.

Control of Penicillin

On the motion for the adjournment on Feb. 25, Sir **John Mellor** submitted that Order 731 which made it a criminal offence to supply penicillin except against a medical prescription was no longer necessary. The medical profession did not contend that direct harm could come from the use of penicillin but that the reaction of the body to it tended to diminish with frequent use. But that was true of many drugs and did not mean that their sale was limited by legislation. Even assuming that some control over the distribution of penicillin should be retained, this order was the wrong way of doing it. There was nothing to justify the use of an order made under the Supplies and Services Transitional Powers Act for 1945 to enforce the medical opinion of the Ministry of Health. He agreed that it was wise to hearken to medical opinion. But it was one thing to say medical opinion should be respected and another to enforce it by law. People should be free to follow medical opinion or to disregard it.

Mr. **John Lewis** suggested that penicillin should not be used here indiscriminately while it was needed in other parts of the world. Penicillin tablets of 500 units, which could be bought without a doctor's certificate in any chemist's shop, were an utter waste of penicillin, for the tablets had not the slightest effect. Again, penicillin creams were being used indiscriminately in dermatology, though they were not a panacea. Wing-Commander **Roland Robinson** feared we were using penicillin as a pawn in the export drive. The Ministry of Supply and the Board of Trade were using it to get hard currency, when it might well be employed at home to improve the health of the people. Dr. S. **Jeger** pointed out that whenever a new drug achieved a fair proportion of cures the public got the idea that it was a cure-all and wanted it for all sorts of things for which it was no use. Again, when a doctor issued a prescription he did not just order a supply of a drug; he also gave instructions for the method of application.

Mr. W. **Leonard**, joint parliamentary secretary to the Ministry of Supply, assured the House that there was now no serious risk of supplies of penicillin being insufficient to meet the medical, dental, and veterinary needs in this country, and during January we had been able to export 85,000 mega units. If control had been removed too early there might have been a sudden expansion of demand and we should have been short of penicillin for important medicinal uses. Indeed, in America it had been found necessary to reimpose control. The position in this country was now so improved that it would no longer be necessary to retain control over distribution on supply grounds. But the Minister of Health had been advised by his medical experts, including Sir Alexander Fleming, that there would be considerable danger in the uncontrolled use of penicillin. There was a real danger to patients and to others of rendering strains of some organisms resistant to penicillin. A draft Bill had been prepared to control the sale and supply of penicillin other than by order.

QUESTION TIME

Penicillin Supplies

Mr. **Somerville Hastings** asked the Chancellor of the Duchy of Lancaster whether his attention had been called to the fact that, except for the treatment of venereal disease, no penicillin is available for use in children's hospitals in the British zone of Berlin; and what action he had taken, or proposed to take.—Mr. J. **Hynd** replied: Since Dec. 1 five mega units of penicillin have been made available each month to the British sector of Berlin from official sources, for the treatment in hospitals, including children's hospitals, of serious cases of other than venereal disease. In addition 175 mega units have been allocated from very considerable supplies made available for the same purposes by "Save Europe Now" and the British medical profession. The possibility of producing penicillin under licence in Germany is being examined in consultation with the American authorities.—Mr. **Hastings**: Is the Minister aware that letters have appeared in the press pointing out how great the shortage is in our zone of Berlin ?—Mr. **Hynd**: There has, of course, been a great shortage of penicillin, and it has been difficult for Germany to get into the queue at all. But supplies received since Dec. 1 have met requirements.

Number of Service M.O.s

Mr. E. M. **King** asked the Minister of Defence how many medical officers there are per 1000 men in the Royal Navy, the Army, and the Royal Air Force, respectively; how many non-specialist medical officers hold specialist posts in these Services; and whether the proportions in South-East Asia are similar to those in other commands.—Mr. A. V. **Alexander** replied: The numbers of medical officers per 1000 personnel in each of the three Services are as follows:

	World-wide	*S.E. Asia*
Royal Navy	3·25	4·4
Army	2·75	2·75
Royal Air Force	3·03	3·9

The figures take into consideration members of the women's Services, but not families. The ratio in theatres other than S.E. Asia is dependent on the distribution of personnel and other factors, and varies accordingly. Non-specialist officers are not employed in specialist posts.

Replying to a further question, Mr. J. **Dugdale** stated that the ratio of medical officers to total personnel of the Navy at the close of the war in Europe was approximately 3 per 1000.

Mr. **Philip Noel-Baker** also stated that at the end of the war in Europe there was 1 medical officer in the R.A.F. to every 437 officers and other ranks. On Dec. 31, 1946, the proportion was 1 to 330.

Refugee Doctors

Dr. S. W. **Jeger** asked the Minister of Health whether, in view of the fact that a larger number of doctors than is at present available is necessary to implement his new national medical service next year and in view of the fact that the Central Medical War Committee has passed a resolution on this subject, he was now in a position to state his policy on the admission of refugee doctors with foreign qualifications to practise in this country.—Mr. A. **Bevan** replied: The views of the Central Medical War Committee on this matter were sought by the Home Office, acting in consultation with my department. I understand that the committee are consulting certain other professional bodies before communicating their views to the Home Office and I am not in a position to make any statement until these have been received and considered.

Medical Certificates for Vacuum Flasks

Sir E. **Graham-Little** asked the President of the Board of Trade on what grounds his department refused to supply a vacuum flask to a patient on a doctor's certificate until the doctor furnished a description of the exact nature of the illness; and whether this description, when furnished, was referred to a medical advisory committee.—Sir **Stafford Cripps** replied: Serious difficulties in obtaining components made it necessary to limit the issue of permits under the distribution scheme which is voluntarily run by Thermos (1925) Ltd. Insufficient flasks were available to allow the issue of permits against all medical certificates presented and it was decided that the only way to ensure that at least the most pressing cases were promptly met was to ask doctors to explain why in particular cases flasks were thought to be essential. The arrival of components from abroad has now somewhat eased the position and recently permits have been issued to all applicants furnishing medical certificates. The answer to the latter part of the question is "No."

Mr. L. J. EDWARDS, M.P. for Blackburn, has been appointed parliamentary secretary to the Ministry of Health in succession to Mr. Charles Key. Mr Edwards, who has been parliamentary private secretary to Sir Stafford Cripps, is secretary of the Post Office Engineering Union.

Obituary

THOMAS WILLIAM SHORE

O.B.E., M.D. LOND.

Dr. T. W. Shore, emeritus lecturer on biology at St. Bartholomew's Hospital medical college, who died at Oldham on Feb. 19 at the age of 85, came of a family of scientists, for his father, T. W. Shore, was well known as an archæologist and his brother Lewis Shore, who died in 1944, was a distinguished physiologist. Thomas William Shore was educated at Burnley Grammar School and at Hartley College, Southampton, where his father was principal. In 1879 he entered Barts with an entrance science scholarship, and a year later he took his B.SC., with first-class honours in zoology and botany. A student who fulfilled his promise, he carried off the Brackenbury and Lawrence scholarships, and after qualifying in 1883 he held a house-appointment till in 1884 he was appointed assistant demonstrator and later demonstrator in physiology. In 1886 he became lecturer in comparative anatomy and for some years he held this post along with the lectureship in biology to which he was appointed in 1892. As a teacher he was an outstanding success, for he had the power of making his subject seem very simple and of making unwilling students industrious.

As warden of the residential college (1891–98) and as dean of the hospital (1900–30) his organising ability found scope. With Sir Anthony Bowlby, Sir Wilmot Herringham, and Sir Holburt Waring he was responsible for joining the college ever more closely with London University, till in 1919 university professors of medicine and surgery were appointed and grants made from the University Grants Committee. Shore was also closely associated with the separation of the college from the hospital and gave able assistance in preparing the charter of incorporation which was granted in 1921. During the 1914–18 war he did good work as a member of the Central War Emergency Committee, and he was appointed O.B.E. in 1919. His juniors did not find it easy to get to know him, for he only appeared on official occasions and on the committees, which he managed with consummate skill.

GORDON ORMSBY LAMBERT

M.D. CAMB., F.R.C.P.

Dr. Lambert, consulting physician to the Royal Berkshire Hospital, Reading, died on Jan. 26, at the age of 69.

Educated in British Guiana and at Bedford School, Lambert studied medicine at Cambridge and at Charing Cross Hospital, to which he won a university exhibition. After qualifying in 1901 he held resident posts at Charing Cross Hospital and at the Victoria Hospital for Children, Chelsea, before appointment as resident medical officer at the Gravesend General Hospital. He graduated M.D. in 1906.

In 1913 he went to Reading as medical registrar at the Royal Berkshire Hospital. The next year he was appointed assistant physician, and in the years that followed became successively physician, senior physician, and, on his retirement from the staff in 1942, consulting physician and cardiologist. He was also consulting physician to Henley-on-Thames War Memorial Hospital and cardiologist for the Reading area to the Ministry of Pensions. In 1933 he was elected M.R.C.P. Lond. for published work, and in 1942 he became a fellow. From 1935 onwards he was a governor of Reading School, and for several years was chairman of the health committee of Reading town council.

His numerous publications on diseases of the heart included a monograph, *Cardiovascular Pain as a Biochemical Problem*, published in 1933. In his *Happiness in a Modern World*, which appeared in 1943, he set out his recipe for contentment in a restless age.

A colleague writes: "Lambert was a most careful physician. He was very keen on the hospital, where most of his time was spent; there was hardly a day in the year when he did not visit it. He played an important part in the Reading Pathological Society, of which he was twice president. His chief clinical interest was 'hearts'; and he was the first physician at the hospital to be appointed to take charge of the electrocardiographic department. He took everything very seriously, but had a sense of humour and could tell a good story when the spirit moved him. His outstanding characteristic was conscientious devotion to his work."

ROBERT VACHELL DE ACTON REDWOOD

F.R.C.S.E.

A FAMILY record of 145 years' association with the Rhymney Cottage Hospital was broken on Jan. 3 by the death of Dr. Redwood, who 44 years ago succeeded his father and grandfather as surgeon at the hospital. He died at his country home at Crickhowell, where he had lived for 15 years, in his 68th year. In 1903 he qualified at St. Mary's Hospital and in 1910 he obtained the Edinburgh fellowship. At Rhymney he held many public appointments, being M.O.H., certifying surgeon, vaccination officer, and infant and child-welfare, poor-law, workmen's compensation, and A.R.P. doctor for the district. A freemason, he was divisional surgeon for Monmouthshire for the Order of St. John of Jerusalem, and a serving brother of the Order. During the war, under the Emergency Medical Service, he was part-time surgeon for the county. An all-round sportsman, he played football for St. Mary's Hospital in 1900–01, when they won the international football challenge cup.

Dr. Redwood is survived by his wife.

ANDREW PATERSON

M.A., M.D. EDIN., DIPL. PSYCH.

Dr. Paterson's untimely death is a loss to psychiatry and neurology, which his researches had done much to illuminate. His early training was in philosophy. Having taken a distinguished degree at Edinburgh in philosophy and psychology in 1930, he pursued further studies at Munich. After graduating in medicine in 1935 and holding the post of house-physician at the Royal Infirmary, he worked with Prof. D. K. Henderson as assistant physician at the Royal Edinburgh Hospital for Nervous and Mental Disorders. In 1938 he moved to Cambridge as research assistant in psychiatry to the regius professor—at that time Professor Ryle—and at Addenbrooke's Hospital and in the Cambridge Psychological Laboratory he studied the psychology of abnormal behaviour in human beings and in animals. The war created an opportunity which gave full scope to Paterson's abilities and training: he took the post of pyschiatrist in the Brain Injuries Unit, at Bangour, where the Rockefeller Foundation provided the means for thorough research into the effects of brain damage. In this Paterson was associated with a psychologist, Oliver Zangwill, and their collaboration was most fruitful. A number of solid papers, illuminating the psychological changes associated with cerebral lesions, appeared chiefly in *Brain*; they bore witness to a thorough use of clinical and psychological methods of investigation, and showed also the capacity for broad yet critical generalisation in which Paterson excelled. It was clear that he had much to contribute to the training of neuropsychiatrists, and in 1946 he was appointed physician to the Maudsley Hospital. During his short tenure of this post his scientific approach to psychiatric problems and his capacity for bringing together psychological and clinical data, especially in the field of perception, revealed him as a stimulating teacher for advanced students, who appreciated greatly, as did his colleagues, his engaging personality and sympathetic yet shrewd understanding of human nature. Just before his fatal illness he was planning research into depersonalisation which gave promise of valuable results.

He died on Feb. 11, aged 40.

EDGAR THOMAS INKSON

V.C., D.S.O., M.R.C.S.

Colonel E. T. Inkson, who died on Feb. 19 at the age of 74, won his Victoria Cross in the South African War in 1901, when he carried a severely wounded officer to safety under heavy fire over exposed ground.

Born at Naini Tal, in India, the son of Surgeon-General J. Inkson, of the Army Medical Services, he was educated at Edinburgh Collegiate School and took the Conjoint qualification from University College Hospital, London, in 1898. He early chose the Army as his career and became a surgeon on probation in April, 1899. Ten weeks before the beginning of the South African War he received his commission and he was sent as a medical officer to the Royal Field Artillery. For his services he received, besides his Victoria Cross, three mentions in despatches. During the 1914–18 war Inkson enhanced his fine record by winning the D.S.O., and he was twice mentioned. During these years he was in command of a field ambulance and later of a general hospital. He retired in 1926. He leaves his wife, formerly Miss Ethel Bromley, with a son and daughter.

CHARLES EDWIN WHEELER

M.D. LOND.

Dr. Charles Wheeler, consulting physician to the London Homœopathic Hospital, died on Feb. 2 at the age of 78. Born in Adelaide, where his father, Dr. Henry Wheeler, was then in practice, he graduated B.SC. Lond. in 1889. After studying medicine at Leipzig and St. Bartholomew's Hospital he took his M.B. Lond. with first-class honours in 1892. A short spell of general practice in Kingston followed, after which he became resident medical officer in the Nordrach Sanatorium. Going to the London Homœopathic Hospital in 1904, he joined the honorary staff two years later and retired in 1928.

Wheeler's chief interest was homœopathy—he was for many years editor of the *Homœopathic World*, and was a past president of the British Homœopathic Society, the International Homœopathic League, and the Faculty of Homœopathy—but his knowledge was wide and he never ceased to plead that homœopathy should keep in the main stream of medicine. This view, he believed, was supported by many rediscoveries of modern medicine. An excellent speaker, he was an acceptable lecturer on his own specialty to many orthodox societies.

Medicine to him was one of the arts, and his versatility ensured his interest in the others—notably drama, music, poetry, and painting—his friends including E. V. Lucas, Henry James, John Masefield, Gilbert Murray, and Bernard Shaw. A founder of the Stage Society, he was also associated with Granville Barker at the Court Theatre, where his wife, Miss Ethel Arundel, whom he married in 1895, used to act. He was an omnivorous reader, from shockers to Arnold Toynbee, and his remarkable memory enabled him to cap almost any quotation. Apart from his original writings he produced translations of Dante's *Divine Comedy*, Hahnemann's *Organon*, and Ibsen's plays. A charming companion, the soul of kindliness and graciousness, he was charitable in the best sense of the word, even to examinees.

W. L. T.

WILLIAM DYSON

O.B.E., M.D. VICT.

Dr. William Dyson, who died at his home at Fallowfield on Feb. 5, was Manchester born and bred, and he served his native city as one of her leading dermatologists for 40 years. Born in 1871, the son of John Dyson, he was educated at Rossall School and Owens College. After taking his M.B. at the Victoria University in 1896 he held a house-appointment at the Royal Infirmary, and spent some nine years in general practice at Broseley in Salop before he turned to dermatology. In 1907 he worked in Vienna under Professor Riehl and Professor Finger, and on his return to Manchester the following year he was appointed to the Manchester and Salford Skin Hospital as assistant medical officer, in 1913 becoming assistant physician and in 1919 full physician. His great interest was in pigmentation, and for his M.D. thesis on Cutaneous Pigmentation in Normal and Pathological Conditions he was awarded the gold medal of the Victoria University in 1910. A keen Territorial medical officer, in the 1914–18 war he served overseas in Gallipoli, Egypt, and Palestine, earning an O.B.E. and mention in despatches. In 1920 he was appointed dermatologist to the Manchester Royal Infirmary and he also lectured on the pathology of skin diseases at the university.

Dr. Dyson leaves a widow, the daughter of Dr. Speirs, of Cleator, and three daughters. His only son, William Speirs Dyson, a promising surgeon and a good sportsman, was lost in 1934 on the Lake Rudolph expedition in the Rift Valley of Central Africa.

DR. WHITFIELD

Sir Ernest Graham-Little writes: Arthur Whitfield gave single-minded devotion to dermatology, and was in the line of succession to the outstanding teachers who have adorned that branch of medicine in the past fifty years. Of those I have known he ranks in my mind with Desnier, Brocq, and Darier in France, and in this country with Crocker and Colcott-Fox, to whom he dedicated his textbook. The salient characteristic of all these men, as also of Whitfield, was the reliance on personal individualist experience, upon which sure foundation their writing was based. I remember well that during a visit to the United States in 1919 I was assured by more than one authority that Crocker was still regarded in America as having written the most original and the greatest dermatological textbook in the English language. Whitfield's own handbook, *Skin Diseases and their Treatment*, published some thirty years ago, reveals in every one of its 300 pages the same originality and the same basis of knowledge. It was exhilarating to see him making a diagnosis. With a watchmaker's lens firmly fixed in his right orbit, he would carry out a detailed inspection of the case, using the technique of a Sherlock Holmes; and he would often solve the problem by observing a single lesion which would have escaped the scrutiny of less intent observers. It was his attention to detail, combined with a most extensive experience, that made him so exceptional and acceptable a teacher. The great college of London University, which he served so faithfully and indeed affectionately for so many years, mourns one of its most distinguished sons.

Elliott & Fry

HOWARD EVERSON CHASTENEY

Mr. H. E. Chasteney, who succeeded Sir Wilfrid Garrett at the end of 1945 as Chief Inspector of Factories, died on Feb. 18 from injuries sustained in a street accident. As head of the Factory Department he was intimately concerned with measures designed to improve the health as well as the safety of factory workers. Only a few weeks ago, in reviewing his first annual report, we were describing it as "a document on a subject without intrinsic appeal to many readers, which nevertheless grips the attention by its warm, sometimes anecdotal style." It is tragic that so valuable a career of public service, devoted largely to accident prevention, should have ended thus abruptly.

Chasteney was born in 1888 and educated at Nottingham High School and at Cambridge University where he distinguished himself in mathematics and natural sciences. He entered the Factory Department of the Home Office in 1913, but served in the Royal Engineers during the 1914–18 war. On returning to his job as inspector of factories, he worked in various parts of the country and gained a wide knowledge of industry and the people in it. Promotion came rapidly and he was appointed deputy chief inspector in 1938. During the late war he gave much attention to civil defence, but a notable contribution to industrial health was his chairmanship of a joint committee on the prevention of dust in steel foundries. The first report was published in 1944 and it bears witness to his thoroughness and sound judgment. He was also chairman of a companion committee which later dealt with iron foundries, and at a recent meeting he signed its final report. His engagingly modest and friendly personality, which did much to soften the asperities of official life, will be missed by all who knew him.

Births, Marriages, and Deaths

BIRTHS

ELLIOT.—On Feb. 9, at Edinburgh, the wife of Dr. T. E. Elliot—a son.

GAVEY.—On Feb. 17, in London, the wife of Dr. C. J. Gavey—a daughter.

GORDON.—On Feb. 8, in London, the wife of Dr. John Gordon—a son.

JOHNSTON.—On Feb. 1, at Glasgow, the wife of Dr. George Johnston—a son.

MERRY.—On Feb. 16, in Leeds, the wife of Dr. Christopher Merry, Colonial Medical Service, Trinidad—a son.

MILLS.—On Feb. 7, at Cambridge, the wife of Dr. J. N. Mills—a son.

NELSON-JONES.—On Feb. 11, at North Cheam, Surrey, the wife of Dr. A. Nelson-Jones—a son.

WARREN.—On Feb. 7, the wife of Dr. M. D. Warren—a son.

WYSE.—On Feb. 6, the wife of Major R. W. Wyse, R.A.M.C.—a son.

MARRIAGES

ALLEN—COLLINS.—On Feb. 1, in London, Richard Alfred Allen, M.B., to Joyce Gwendolen Collins, C.S.P.

EDWARDS—COLES.—On Jan. 30, at Kingsteignton, Devon, Joseph Rowland Goodman Edwards, M.B., to Betty Cecelia Coles.

LOVELL—WARREN.—On Feb. 8, at Sarisbury, Richard Robert Haynes Lovell, M.R.C.S., to Diana Warren.

POLLARD—BARKER.—On Nov. 11, at Brompton, Basil Ranson Pollard, M.R.C.S., lieutenant R.A.M.C., to Doreen Barker.

DEATHS

AMBROSE.—On Feb. 28, at Barnt Green, Worcs, William Cole Ambrose, B.A. Camb., M.R.C.S., aged 76.

AYDON.—On Feb. 23, at Stillorgan, Dublin, John Aydon, M.A. Camb., M.R.C.S., of Angmering, Sussex.

BREWER.—On Feb. 9, Henry Jeaffreson Brewer, M.R.C.S., aged 67.

COLYER.—On Feb. 10, Arthur Reginald Colyer, M.R.C.S.

CUMMINS.—On Feb. 8, at Smyrna Beach, Florida, Arthur Gordon Cummins, M.C., M.B. R.U.I., late R.A.M.C.

DARBYSHIRE.—On Feb. 16, at Exmouth, Harold Stewart Cassan Darbyshire, M.R.C.S.

DICKSON.—On Feb. 19, at Hythe, Kent, Robinson Simpson Dickson, O.B.E., M.D. Glasg., aged 78.

DUIGAN.—On Feb. 24, at Oxford, William Duigan, M.B. Camb.

DUNN.—On Feb. 2, William Dunn, M.B. Aberd.

DYSON.—On Feb. 5, William Dyson, O.B.E., M.D. Vict.

EAGER.—On Feb. 2, Richard Eager, O.B.E., M.D. Aberd., aged 65.

FAIRBANK.—On Feb. 23, at Canford Cliffs, Christian Beverley Fairbank, M.R.C.S., surgeon commander R.N. retd.

FEGAN.—On Feb. 27, at Leamington Spa, Richard Ardra Fegan, M.R.C.S., aged 77.

GENGE.—On Feb. 19, at Croydon, George Gilbert Genge, M.D. Lond., D.P.H.

GIBSON.—On Feb. 13, in London, John Basil Aylwin Gibson, M.A. Camb., M.R.C.S., aged 29.

GLADSTONE.—On Feb. 12, Reginald John Gladstone, M.D. Aberd., F.R.C.S., D.P.H., F.R.S.E.

GRAY.—On Jan. 21, at Totana, Murcia, Spain, Albert Germain Gray, M.B. Aberd., aged 70.

HALL.—On Feb. 4, Joseph Percy Hall, M.B. Lond., aged 75.

HENDERSON.—On Feb. 28, Fergus Leslie Henderson, M.B. Glasg.

ILES.—On Feb. 21, Mary Muriel Griffin Iles, M.D. Lond., D.P.H.

INKSON.—On Feb. 19, Edgar Thomas Inkson, V.C., D.S.O., M.R.C.S., colonel, late R.A.M.C., of Chichester.

JAMESON.—On Feb. 18, at Croydon, George Bernard Jameson, M.D. Edin.

JAYS.—On Feb. 2, Tom Jays, M.R.C.S., aged 78.

LANGRISHE.—On Feb. 28, at Edinburgh, John du Plessis Langrishe, D.S.O., M.B., D.P.H., lieut.-colonel R.A.M.C. retd., aged 64.

LEDGER.—On Feb. 7, at Torquay, Alfred Vernon Ledger, M.D. Brux.

MCARTHUR.—On Feb. 24, in London, Neil Murray McArthur, M.D. West Ont., surgeon lieut.-commander R.N.

MACAULEY.—On Feb. 26, at Ealing, Constantine Macauley, L.R.C.P.I.

MACDONALD.—On Feb. 16, at Oban, Duncan Macdonald, M.D. Glasg., aged 74.

MCDOUALL.—On Feb. 3, at Wahroonga, New South Wales, Herbert Crichton McDouall, M.R.C.S., D.P.H., aged 87.

MCGRATH.—On Jan. 28, Liam Henry McGrath, M.B. Belf., wing-commander R.A.F.

MCNEILL.—On Feb. 3, in London, Arthur Norman Roy McNeill, D.S.O., M.B. Glasg., D.P.H., colonel, late R.A.M.C.

MACKENZIE.—On Feb. 25, in London, Harry Malcolm Mackenzie, C.I.E., colonel I.M.S. retd.

MACMILLAN.—On Feb. 26, John McCallum Anderson Macmillan, M.D. Edin., F.R.C.S., lieut.-colonel I.M.S.

PARRY.—On Feb. 24, at Bradninch, Devon, James Hales Parry, M.R.C.S.

PATERSON.—On Feb. 11, Andrew Paterson, M.D. Edin., aged 40.

ROBBS.—On Feb. 7, at Grantham, Charles Haldane Denny Robbs, M.B. Lond., aged 72.

SELBY.—On Feb. 26, Prideaux George Selby, O.B.E., M.R.C.S., of Lynsted, Kent, aged 81.

SHORE.—On Feb. 19, at Oldham, Thomas William Shore, O.B.E., B.SC., M.D. Lond., F.R.C.S., aged 85.

SISAM.—On Jan. 27, William Sisam, M.D. Birm., D.P.H., aged 71.

WHEELER.—On Feb. 2, Charles Edwin Wheeler, B.SC., M.D. Lond., aged 78.

WIMBLE.—On Feb. 28, at Bushey, Herts, Herbert Charles Wimble, M.R.C.S., aged 80.

Notes and News

RHEUMATISM RESEARCH

AT the annual meeting of the Empire Rheumatism last December, Lord Horder, its president, announced t the council was undertaking a careful survey of some of cases of rheumatoid arthritis, with the aim of finding for specific research. Studies of this and of other conditions, if they are to be effective, must be nation and large funds are needed. The council now appeals £100,000 to enable the work to be carried through.

Manchester University, which produced a scheme some months ago (*Lancet*, 1946, ii, 609), is to appoint a clinical director of its research centre, at a salary of £1500–£2000 a year.

DIAGNOSIS OF VIRUS INFECTIONS

IN a Chadwick lecture on Feb. 18 Prof. S. P. Bedson, F.R.S., said that in virus work insufficient use is made of new diagnostic procedures. It is still widely-believed that all viruses are too small to be seen with the microscope, yet in quite a number of diseases microscopical demonstration of the causal virus is of diagnostic value. This is true of trachoma and of those conditions caused by the related virus of inclusion conjunctivitis; the virus of lymphogranuloma venereum can at times be demonstrated in smears made from inguinal buboes; and recent work has shown the usefulness of examining smears from the skin lesions of smallpox. Even where the virus cannot be seen, histological changes such as inclusion bodies can be looked for; their occurrence is always suggestive of virus infection, and sometimes, as with the Negri body in rabies, it is diagnostic.

It is still not generally appreciated, said Professor Bedson, that the serological reactions employed in bacteriology are equally applicable to the identification of viruses or the diagnosis of virus disease. Of these reactions the complement-fixation test is probably the most valuable; it can be used either to demonstrate the presence of the causal virus, as in smallpox, or for the detection of antibody, as in influenza, psittacosis, lymphocytic choriomeningitis, lymphogranuloma venereum, and mumps.

REABLEMENT FILM

A COLOURED documentary film dealing with the work at Roffey Park Rehabilitation Centre was given its first public showing at the London School of Hygiene on Feb. 27. Queen Mary was present, and this is said to be the first time that a scientific film has been accorded a Royal première. The film, which was made for the National Council for the Rehabilitation of Industrial Workers by Messrs. Kodak Ltd. and Associated British Pictures Corporation, is meant primarily for the industrial organisations which have used or are otherwise interested in this centre. It is therefore addressed to laymen, but it will have a wide appeal to doctors, for it shows the inter-relation of purely medical treatment with all the other facets of the work. This it does by following the passage through the centre of a man and woman who have broken down in industry, up to their return to work. The film is perhaps a little too idyllic, but nevertheless deserves an extensive showing as illustrating the short-term approach to problems of industrial maladjustment.

University of Cambridge

On Jan. 31 the following degrees were conferred:

M.D.—J. R. Bolton, R. F. Tredgold, B. J. O. Winfield, A. R. Kelsall, W. H. Tattersall.

M.B., B.Chir.—*A. V. Adams, *E. M. M. Besterman, *Gerald Raperport, *James Fiddess, *Desmond Seymour, *E. B. Davies, *P. A. Emerson, *A. D. R. MacAuslan, *James McMillan, *J. J. Morland, *J. C. Ward, J. A. Elliott, *D. C. Bradford, *R. J. Alcock, *P. W. S. Coghill, *C. S. Kirkham, *E. D. Marsh, *J. P. Paul, *J. P. Stephens, *A. D. Thomson, W. J. B. Rogers, E. S. O. Smith, *C. P. Bennett, *A. O. Chase, *W. M. B. Strangeways, *D. A. L. Bowen, *T. W. Backhouse, *J. P. Bull, *P. W. Rowsell, R. H. C. Robins, *J. H. Steeds, *D. W. Burnford, *K. G. Irving, *J. F. F. Rooney, *J. E. H. Stretton, *John Crossley, *G. R. Freedman, *I. S. M. Jones, *K. S. Murray, D. G. Miller, I. R. D. Proctor, *L. C. Lancaster, *H. E. S. Marshall, *Kenneth Till, *M. F. Smith.

* By proxy.

The titles of the degrees of M.B., B.Chir. have been conferred on Mrs. S. M. Godfrey.

University of Manchester

Mr. D. G. Evans, PH.D., has been appointed reader in chemical bacteriology, and Dr. R. A. Bailey and Miss Eugenie Willis, F.R.C.S., clinical demonstrators in anatomy.

University of Sheffield

Dr. Llywelyn Roberts has been appointed honorary lecturer in public health, Dr. J. Wilkie honorary lecturer in radiological anatomy, and Dr. Leslie Cook honorary lecturer in bacteriology.

Royal College of Surgeons of England

At a meeting of the council of the college, held on Feb. 13, with Sir Alfred Webb-Johnson, the president, in the chair, Prof. Louis Bazy, of Paris, was enrolled as an honorary fellow.

Mr. Neil Sinclair (West London), Mr. T. Twistington Higgins (Great Ormond Street), and Sir Stanford Cade (Westminster) were re-elected members of the court of examiners, and Mr. W. Kelsey Fry a member of the board of examiners in dental surgery. Prof. F. Wood Jones, F.R.S., was appointed Arris and Gale lecturer, and Dr. R. J. Last and Mr. H. F. Lunn, Arnott demonstrators. Sir Cecil Wakeley was appointed chairman of the editorial committee of the forthcoming *Annals of the Royal College of Surgeons of England.*

The Hallett prize for anatomy, applied physiology, and pathology was awarded to H. J. Richards (University of Sydney). Diplomas of membership, in public health, and in laryngology and otology, were granted to those named at the comitia of the Royal College of Physicians (*Lancet*, Feb. 8, p. 230). The diploma of M.R.C.S. was also granted to P. J. Horsey and F. S. Huxley, and the D.L.O. to R. T. Raymond-Jones.

Royal College of Physicians of Edinburgh

At a meeting of the college on Feb. 4, with Dr. D. M. Lyon, the president, in the chair, Dr. H. J. Parish (Petts Wood, Kent), Dr. R. C. Wood (Edinburgh), and Dr. J. A. Malloch (Edinburgh) were admitted as fellows, and Dr. W. A. Liston (Edinburgh) was elected to the fellowship. The following were elected to the membership:

J. M. Henderson, Nawab Ali, Sujata Chaudhuri, Isidore Schrire, J. P. Baird, Charles Groves, William Hunter, Jacob Du Toit, R. L. Tobias, A. O. Watt, H. M. Khan, R. W. Riddell, Vera S. Emanuel, Cecil Harris, H. C. Hastings, A. R. Currie.

Psychiatric Conference at Amsterdam

The Dutch Society of Psychiatry and Neurology are holding an international meeting in Amsterdam from June 13 to 15, to celebrate their 75th anniversary. English psychiatrists and neurologists who wish to attend should get in touch with the secretary of the Royal Medico-Psychological Association, 11, Chandos Street, London, W.1, before April 15.

Hunterian Society

The society's annual dinner, marking this year the 219th birthday of John Hunter, was held in London on Feb. 13. Among the guests were the Lord Mayor and Lady Mayoress, and the presidents of the three Royal Colleges. Replying, as president, to the toast of The Society, Dr. J. B. Cook recalled that whereas John Hunter's birthday is commemorated by the society on Feb. 13 each year, the Royal College of Surgeons celebrate the anniversary on the 14th. Hunter himself gave his birthday as the 14th; but a copy of the birth-certificate obtained by Dr. Cook from the Registrar-General in Edinburgh establishes that the correct date is the 13th. Mr. A. Dickson Wright, in proposing The Lord Mayor and the Corporation of the City of London, suggested that at the next annual dinner all fellows would be in uniform.

Postgraduate Teaching Hospitals

At a meeting of representatives of special hospitals organised for postgraduate teaching, held at the Hospital for Sick Children, Great Ormond Street, London, on Feb. 11, with Sir Ernest Gowers in the chair, it was unanimously decided to set up a representative body, to be known as the Association of Postgraduate Teaching Hospitals of Great Britain. Membership of the association is limited to hospitals or groups of hospitals having directly attached to them institutes federated or about to be federated to the British Postgraduate Medical Federation (University of London) or to provincial hospitals with institutes recognised and financially supported by a university as postgraduate teaching centres. The objects of the new association are "to keep under review all matters peculiarly affecting the interests of the member hospitals, and to act as a negotiating body directly with the Ministry of Health, universities, local authorities and other bodies on behalf of those hospitals on such matters as may peculiarly affect them." The acting hon. secretary is Mr. John Young, Royal National Throat, Nose, and Ear Hospital, Gray's Inn Road, W.C.1.

Polish Medical School

This school, which has been at the Paderewski Hospital, Edinburgh, since 1941, will shortly be moved to Poland, where it is proposed to provide a hospital of 2000 to 3000 beds.

Institute of Hospital Almoners

The annual general meeting of the institute will be held at Friends House, Euston Road, London, N.W.1, on Friday, March 14, at 6 P.M., when Dr. J. A. Charles, deputy chief medical officer of the Ministry of Health, will speak.

Course in Industrial Medicine

A course in industrial medicine will be held at the University of Leeds on Saturday and Sunday, May 3 and 4. The speakers will include Dr. A. J. Amor, Prof. G. P. Crowden, Dr. G. R. Hargreaves, Dr. F. F. Hellier, Dr. J. Vaughan Jones, and Dr. C. Sutherland. Further particulars will be found in our advertisement columns.

Arthur Davies Research Fund

This fund, which was founded to further research for the benefit of officers and men of the Mercantile Marine, has appointed Dr. Geoffrey Allen as a part-time worker at the Devonport pathological laboratories of the Dreadnought Seamen's Hospital, Greenwich. Dr. Allen has chosen fungal skin disease as the subject of his research.

Reunion of Army Physicians

A reunion dinner for former C.M.F. and M.E.F. physicians (including neurologists, dermatologists, psychiatrists, and radiologists) will be held at Grosvenor House, Park Lane, London, W.1, on Saturday, April 26, at 7.30 P.M. Applications should be sent not later than March 31 to Dr. W. MacLeod, 3, Drumsheugh Gardens, Edinburgh, or to Dr. A. Willcox, 66, Harley Street, W.1.

World Health Organisation

The organisation has inherited a fund of $1^1/_3$ million dollars which is to be used in partial continuation of UNRRA's activities. Provisional allocations have now been made from this fund to continue the teaching programme in China and the basic health training in Ethiopia; for fellowships in eight countries; for supplying lecturers and medical literature; and for contributions to the salaries of specialists at the New York and Geneva offices of the interim commission of the organisation.

Honorary Consultants

In recognition of their service as consultants to G.H.Q., India, during the war, the following to be honorary consultants to the India and Burma Offices:—

Brigadier S. M. Hepworth (radiologist); Brigadier G. W. Bamber (dermatologist); Brigadier E. E. Prebble (venereologist); Brigadier D. McAlpine (neurologist); Brigadier E. A. Bennet (psychiatrist); Brigadier H. K. Ashworth (anæsthetist); Brigadier G. F. O. Bridgeman, M.C. (ophthalmologist); Brigadier Grant Massie, C.B.E. (surgeon); Brigadier J. D. S. Cameron, O.B.E. (physician).

Society of Chiropodists

The first convention of the society will be held at Friends House, Euston Road, London, N.W.1, from March 20 to 22. Sir Hugh Lett will open the meeting on Thursday, the 20th, at 2.30 P.M., and other medical speakers will include Prof. A. B. Appleton, whose subject will be Posture, Mr. Philip Wiles (Pain and Deformity of the Metatarsals and Toes), Mr. Denis Browne (Deformities of the Feet in Children), Prof. A. J. E. Cave (the Foot as a Sensory Organ), and Dr. Allan Yorke (Hyperkeratosis of the Sole of the Foot). Further information may be had from the secretary of the society, 21, Cavendish Square, London, W.1.

Canadian Appointment

Dr. A. B. Stokes is resigning his post as medical superintendent of the Maudsley Hospital on his appointment as professor of psychiatry and physician-in-chief of the Toronto Psychiatric Hospital.

Dr. Stokes, who took the Conjoint qualification at King's College Hospital in 1931 and his B.M. Oxfd three years later, joined the staff of the Maudsley Hospital in 1935. On the outbreak of war he was appointed deputy medical superintendent of Mill Hill Emergency Hospital, later becoming medical superintendent, and in 1945, when the Maudsley Hospital was reopened, he was appointed to his present post. His published work includes papers on the treatment of myasthenia gravis and on mental disorder in Cushing's syndrome.

Biochemical Society

A meeting of the society will be held at Guy's Hospital medical school on Saturday, March 15, at 2.30 P.M.

Research Scholarships

The council of the British Medical Association is prepared to receive applications for the following scholarships: an Ernest Hart scholarship (value of £200), a Walter Dixon scholarship (£200), and four research scholarships (each £150). Scholars should be qualified to undertake research in any subject (including State medicine) relating to the causation, prevention, or treatment of disease, and preference will be given to doctors. Each scholarship is tenable for one year, beginning on Oct. 1, 1947. A scholar may be reappointed for not more than two additional terms, and he may also hold a junior appointment at a university, medical school, or hospital, provided the duties do not interfere with his work as a scholar. *Application must be made by May 31, on a prescribed form* which may be had from the secretary of the association, B.M.A. House, Tavistock Square, London, W.C.1.

Return to Practice

The Central Medical War Committee announces that the following have resumed civilian practice:

Dr. T. R. Lloyd Jones, 17, Queen Anne Street, London, W.1 (Langham 2576).

Dr. R. Louis Rose, 118, Newmarket Road, Norwich.

Lieutenant-General Sir Alexander Hood, F.R.C.P., has been elected chairman of governors of the Star and Garter Home for Disabled Sailors, Soldiers, and Airmen, Richmond, in place of Sir Arthur Stanley, who has resigned.

Dr. H. P. Chu, dean of the National Medical College, Shanghai, and formerly secretary of the Chinese Medical Association, has arrived on a three months' visit to this country arranged by the British Council. He is studying medical education and the training of nurses.

The firm of Ciba Limited has changed its name to Ciba Laboratories Limited.

Diary of the Week

MARCH 9 TO 15

Monday, 10th

Royal College of Surgeons, Lincoln's Inn Fields, W.C.2
3.45 P.M. Dr. L. E. Glynn: Aneurysms and Aneurysm Formation.
5 P.M. Prof. Frank Goldby: Intracranial Anatomy of the Trigeminal Nerve.
Medical Society of London, 11, Chandos Street, W.1
8.30 P.M. Dr. Horace Evans, Mr. Geoffrey Keynes: Thyrotoxicosis.

Tuesday, 11th

Royal College of Surgeons
3.45 P.M. Dr. P. R. Peacock: Ætiology of Gastric Cancer.
5 P.M. Professor Goldby: Anatomy of the Optic Pathways.
Royal Society of Medicine, 1, Wimpole Street, W.1
5 P.M. *Experimental Medicine and Therapeutics.* Brigadier J. S. K. Boyd, Prof. N. Hamilton Fairley, F.R.S.: New Antimalarials and Malarial Control.
5.30 P.M. *Psychiatry.* Dr. Russell Davis: Disorders of Skill.
London School of Dermatology, 5, Lisle Street, W.C.2
5 P.M. Dr. F. R. Bettley: Eczema.
Edinburgh Postgraduate Board for Medicine
5 P.M. *(Royal Infirmary.) Prof. J. H. Gaddum,* F.R.S.: *The* Introduction of New Remedies.

Wednesday, 12th

Royal College of Surgeons
3.45 P.M. Prof. Alexander Haddow: Carcinogenesis by Chemical Agents.
5 P.M. Prof C. M. West: Reproductive System.
Royal Society of Medicine
4.30 P.M. Mr. H. E. Griffiths: Analysis of Function.

Thursday, 13th

Royal College of Surgeons
3.45 P.M. Professor Haddow: Nature and Rôle of Tumour-producing Viruses.
5 P.M. Professor West: Reproductive System.
Royal Society of Medicine
5 P.M. *Ophthalmology.* Mr. O. Gayer Morgan, Dr. C. J. C. Britton, Dr. J. T. Ingram: Allergy in Ophthalmology.
London School of Dermatology
5 P.M.: Dr. J. L. Franklin: Occupational Diseases of the Skin.

Friday, 14th

Royal College of Surgeons
3.45 P.M. Mr. J. R. M. Innes, D.SC.: Animal Pathology.
5 P.M. Dr. T. E. Barlow: Bronchial Tree.

Appointments

Elliot, T. E., M.B. Edin., F.R.C.S.E.: asst. gynæcologist, Leicester Royal Infirmary.
Gordon, G. A. D., M.B. Edin., D.M.R.: radiologist, Bolingbroke Hospital, London.
Hyman, Geoffrey, M.B. Leeds, F.R.C.S.: visiting orthopædic surgeon, Royal Halifax Infirmary.
Le Vay, Marjorie K., M.B. Camb.: pathologist, South London Hospital for Women.
McLardy, Turner, M.B.E., M.B. Glasg.: asst. pathologist for neuropathology at the teaching and research laboratory, Maudsley Hospital medical school.
Moore, H. E., O.B.E., M.B. Manc.: M.O. and *acting chief M.O.* London, Midland, and Scottish Railway, Crewe.
Newnham, C. T., M.R.C.S.: asst. to chief M.O., Great Western Railway.
Rowntree, J. K., M.R.C.S.: asst. M.O., Great Western Railway, Swindon.
Rubin, E. L., M.D. Lpool, D.M.R.E., F.F.R.: radiologist, Royal Liverpool United Hospital.
Thomas, D. T., M.R.C.S., D.P.H.: M.O.H., Penarth.
Williams, B. W., B.M. Oxfd, F.R.C.S.: asst. surgeon, Royal Portsmouth Hospital.

London County Council:
Duke, J. H., M.B. Belf.: medical superintendent, group IV, St. George-in-the-East Hospital, Wapping.
Key, L. A., M.R.C.S.: medical superintendent, group IV, Heatherwood Hospital, Ascot.
Peckar, V. G., M.B. Lond., D.M.R.D.: radiodiagnostician, Lambeth Hospital and St. Charles' Hospital, Kensington.
Piercy, J. E., F.R.C.S.: medical superintendent, group IV, New End Hospital, Hampstead.
Ross, G. M., M.B. Edin., D.M.R.: asst. radiodiagnostician, Hammersmith Hospital.
Whetnall, Aileen E. M., M.S. Lond., F.R.C.S.: consultant aural surgeon, public health department.
Wimbush, H. G., M.R.C.S.: medical superintendent, group III, Hammersmith Hospital.

Connaught Hospital, London:
Bentley, J. P., M.B. Lond., F.R.C.S.: surgeon.
Fathi, J. T., M.S. Lond., F.R.C.S.: surgeon.
Rigby-Jones, Guy, M.C., M.B. Camb., F.R.C.S.E.: asst. orthopædic surgeon.
Wilkinson, L. H., M.A. Oxfd, M.B. Edin.: physician i/c electrotherapeutic department.

Hospital for Consumption and Diseases of the Chest, ***Brompton:***
Brock, R. C., M.S. Lond., F.R.C.S.: surgeon.
Thomas, C. P., F.R.C.S.: surgeon.

King Edward Memorial Hospital, Ealing:
King, R. A., M.B. Lond., F.R.C.S.: surgeon.
Webb, John: physician to children.

Royal Northern Hospital, London:
Owen, J. R., M.R.C.P.: physician for diseases of the skin.
Williamson, Bruce, M.D. Edin., F.R.C.P.: physician to children's department.

Croydon General Hospital:
Ayoub, J. E. M., B.M. Oxfd, F.R.C.S.: asst. ophthalmic surgeon.
Hamilton, J. G., M.D. Lond., D.P.M.: psychiatrist.
Hindenach, J. C. R., M.D. N.Z., F.R.C.S.: orthopædic surgeon.
Ives, John, M.B. Lond., D.A.: anæsthetist.
Owen, M. W. L., M.B. Camb., D.A.: anæsthetist.
Pierse, D. J., M.CH. N.U.I., D.O.M.S.: asst. ophthalmic surgeon.
Robertson, Ivor, M.B. Lond., F.R.C.S.E., D.L.O.: asst. orthopædic surgeon.
Taylor, J. H., M.R.C.S., D.A.: anæsthetist.
Turner, J. W. A., D.M. Oxfd, M.R.C.P.: neurologist.

Surrey County Council:
Greig, D. S., M.D. St. And., M.R.C.O.G.: obstetrician and gynæcologist, St. Helier County Hospital.
Lavelle, John, M.B. Glasg., D.M.R.E.: radiologist, St. Helier County Hospital.
O'Reilly, J. N., D.M. Oxfd, M.R.C.P: pædiatrician, St. Helier County Hospital.
Petch, C. P., M.B. Camb, M.R.C.P.: asst. physician to out-patients, St. Helier County Hospital.
Roussel, O. N., M.D. Camb., D.A.: *senior* anæsthetist, Epsom County Hospital.
Stewart, J. D., M.B. Edin., D.P.H., D.PHYS.MED.: director, department of physical medicine, St. Helier County Hospital.

Children's Hospital, Birmingham:
Crosskey, J. H., M.B. Birm., D.P.H.: anæsthetist.
D'Abreu, A. L., O.B.E., CH.M. Birm., F.R.C.S.: surgeon to out-patients.

Cardiff City Mental Hospital:
Rees, W. L. L., B.SC., M.D. Wales, M.R.C.P., D.P.M.: deputy physician superintendent.
Richter, Derek, B.SC., M.A. Oxfd, M.R.C.S.: director of neuro-psychiatric research.

Examining Factory Surgeons:
Bevan-Jones, D. H. B. M.R.C.S.: Llanaelhaiarn.
Jones, E.: Crewe.
Lethem, Edward, M.R.C.S.: Derby.
Robinson, William, M.B. Glasg.: Costock, Notts.
Taylor, Gordon, M.R.C.S.: Yealmpton, Devon.

Colonial Service:
Cherry, J. K. T., M.B. Glasg.: M.O., Uganda.
Tallack, R. J. K., M.B. Brist.: M.O., Zanzibar.
Young, K. D., M.R.C.S.: M.O., Zanzibar.

ATOMIC ENERGY*

Sir JAMES CHADWICK
M.Sc. Vict., Ph.D. Camb., F.R.S.
LYON JONES PROFESSOR OF PHYSICS, UNIVERSITY OF LIVERPOOL

THE designations "atomic energy," "atomic bomb," &c., which are now in common use are somewhat lacking in precision. In the strict meaning of the term the energy which is derived from fuel of any kind is atomic energy. The energy obtained from the combustion of coal or oil is latent in the atoms of carbon and oxygen. These atoms, like all atoms, are built up on a common plan. Every atom, whatever its kind, consists of a cluster or cloud of electrons held together by the attraction of a positively charged nucleus, which, although it contains nearly the whole mass of the atom, is extremely small compared with the dimensions of the electron cloud. The atoms of one element differ from those of another in the magnitude of the electric charge on the nucleus and therefore also in the number of electrons in the cluster. The charge on the nucleus increases from 1 unit in the case of hydrogen to 2 for helium, and so on up to 92 in the case of uranium. The nucleus itself, although so minute, is a complicated structure, built up from protons and neutrons. It is thus possible to build two or more nuclei which have the same charge, and therefore belong to the same element, but which have different masses; in this way the occurrence of isotopes receives a simple explanation.

All the ordinary properties of matter, such as hardness, electrical conductivity, chemical affinity, &c., are determined by the configuration of the electron cluster and are practically independent of the structure of the atomic nucleus. Thus all the chemical and physical processes involved in normal scientific and industrial developments are concerned with the electron clusters alone.

This is because the usual physical and chemical agencies produce no change whatever in the properties of the nucleus and affect only the electron cloud. But what we are now accustomed to call "atomic energy" has its origin in the atomic nucleus. Processes have been found which can cause a disruption of the nucleus and a rearrangement of the particles which constitute it; and this rearrangement results in the release of a large amount of energy.

HIDDEN RESERVES OF ENERGY

The story of the development which led to our present knowledge of the nucleus and its properties goes back fifty years, to the discovery of radioactivity by Becquerel in 1896.

This discovery opened a new epoch of science, for, as Rutherford and Soddy showed, the phenomena of radioactivity could only be explained by the assumption that the atoms of uranium, radium, &c., were unstable and were continuously breaking up and changing into other elements.

One of the most striking facts in these phenomena is the amount of energy released in the form of radiation, an amount which, atom for atom, is enormously greater than that connected with any chemical reaction. This energy released had, however, no practical value, for the rate of release is very slow and it proved to be impossible to influence it in any way. For example, in the decay of 1 g. of uranium, energy is emitted at the rate of rather less than 1 calorie per year, so that it would take more than 100 years to raise 1 c.cm. of water to the boiling point. On the other hand, the lifetime of uranium is so long that the total amount of energy liberated during the transformation of 1 g. of uranium to lead would be 5,000,000,000 calories. We can compare this with the complete combustion of 1 g. of coal, which gives 8000 calories.

It became clear that there is a reservoir of energy in the interior of the atoms of matter which is enormously greater than that available from any known chemical process. But all attempts to influence the rate of transformation of a radioactive element proved futile and the prospect of any practical application seemed exceedingly remote.

The first successful attempt to affect the atomic nucleus was made by Rutherford in 1918, when he showed that when nitrogen was bombarded by the α-particles from radium C the nucleus in rare instances broke up, forming two other nuclei—hydrogen and oxygen.

After this discovery several other elements were transmuted by similar means, and later it was found that protons and deuterons, accelerated to high speeds in strong electric fields, also produced transmutations in many common elements. The neutron proved to be almost an ideal projectile for carrying out nuclear transformations, and, with it, nearly all the elements have been transmuted. In some cases, especially with slow neutrons, the reactions were very efficient.

Many interesting and even remarkable results in their scientific aspect were obtained in these experiments. But their practical value, as a means of making available the energy stored in the nuclei of atoms, was completely negligible.

The reason was simple. These nuclear transmutations are not only very rare events but they are not self-propagating. This is quite different from the chemical reactions with which we are familiar in our daily life, such as the burning of wood, coal, or oil. Once started, these reactions propagate themselves and they develop and spread, finally involving the whole bulk of material; thus the lighting of a fire releases enough heat to ignite the neighbouring fuel, and so on.

This was not the case for the nuclear reactions. It is clear that to tap the hidden reserves of energy in atomic nuclei and put them to practical use we must find a reaction which can propagate itself—for example, a reaction in which particles are emitted of the same kind that initiated it and in sufficient numbers to affect neighbouring nuclei, so that these in their turn may emit new particles to react with other nuclei, and so on, thus beginning a chain reaction which spreads through the whole mass.

NUCLEAR FISSION

The reaction which opened up this possibility was discovered early in 1939, when Hahn and Strassmann showed that the transformation of uranium produced by neutron bombardment was a very different process from what had hitherto been supposed, and that the uranium nucleus actually splits into two fragments of roughly equal mass.

This process is known as fission. A neutron is captured by a nucleus of uranium 235, forming a nucleus of uranium 236 in a highly excited state. This immediately divides into two nuclei of roughly equal mass and at the same time some 1 to 3 neutrons are emitted and some γ-radiation. The fragments fly apart with great speed, and, in their passage through matter, this energy of motion is transformed into heat. These fragments are unstable and may pass through a series of transformations emitting β-particles and γ-radiations, before they at last reach a stable configuration.

There are two important aspects of the fission process. First, a great amount of energy is released; secondly, more than one neutron is emitted in the fission. This second point is of crucial significance, for it is this which opens up the possibility that the reaction can be propagated from atom to atom, developing a whole chain of fissions from one single event. Such a chain process developing in a mass of uranium might take place at an ever-increasing rate and might involve so many atoms that there would be an appreciable, and possibly an overwhelming, liberation of energy. In this way we might get a new type of combustion of matter which would give an energy yield a million times greater than we get from the combustion of the same weight of coal.

---

* Lloyd Roberts lecture delivered to the Medical Society of London on Dec. 16, 1946.

Investigation showed that natural uranium is unable by itself to sustain a chain reaction. The reason for this is that the common isotope 238, which forms more than 99% of natural uranium, undergoes fission only when the bombarding neutrons have a high energy; it is the isotope 235 which is particularly susceptible to fission, and this is present in natural uranium only to the extent of 0·7%.

In order to make a small and efficient system which would sustain a chain reaction it was therefore necessary to separate uranium 235 from ordinary uranium. This separation is a very difficult operation since the two isotopes are almost identical in every property but that of mass, and even in mass they differ by little more than 1%. Nevertheless the separation has been accomplished in two different ways, by an electromagnetic method and by a gaseous diffusion process, and both processes have provided adequate amounts of uranium 235.

This uranium 235 can be used to make an atomic bomb, in which the energy is released so rapidly that a violent explosion occurs, or it can be used in such a way as to release the energy gradually.

For many purposes, and especially for those purposes which are of interest in biology and medicine, it is of little importance to have a system of small size. If this limitation is removed, it is possible, by a special device, to build an atomic reactor which uses natural uranium and so to avoid the need for the very difficult and very costly separation of the isotopes. Before describing how this is done, I must make some general observations on the chain reaction and the conditions for its realisation.

MAINTENANCE OF CHAIN REACTION

Suppose we have a large block of fissile material and that a neutron enters and causes one of the nuclei to undergo fission. Energy will be released and two neutrons will be produced. These two neutrons will move through the block until each eventually hits another nucleus. We now have two fissions, liberating more energy, and four neutrons. These in turn produce fissions, so that we have a series of successive generations of energy and neutrons. The number of neutrons, and therefore also of fissions, is doubled in each generation, so that in quite a small number of generations, between 50 and 100, an appreciable fraction of the atoms of the block will undergo fission and a large amount of energy will be set free.

The multiplication of the effect in successive generations clearly depends on the conservation of the neutrons produced in the fissions. If too large a fraction of these neutrons is unable to carry on the chain of fissions the reaction will die out quickly and the amount of energy released will be negligible. Neutrons can be lost in two ways. First, the block of fissile material, or the reacting system as a whole, may be too small or its shape may be unsuitable; in this case too many neutrons will be able to escape out of the block before they are able to produce further fissions. The proportion which escape can be reduced by increasing the size of the block, and there will be a certain size, called the critical size, which will just permit the reaction to develop. There is thus a striking difference in behaviour between an atomic explosive and ordinary explosive. A small amount of T.N.T. produces a small explosion and a large amount produces a large explosion. But a small piece of fissile material produces no effect whatever; an explosion will only occur when the amount is greater than the critical size.

Secondly, the system must not contain more than a limited amount of material which absorbs neutrons without undergoing fission, for in this way again the neutrons will be wasted and useless for continuing the chain reaction.

These two conditions must be satisfied before a chain reaction can develop.

If atomic energy is to be used as an explosive, the more rapidly the reaction can proceed the greater will be the amount of energy set free and therefore the greater the explosive effect. It is thus an advantage to use pure or nearly pure uranium 235 (or plutonium, another fissile material). The fission neutrons have speeds of the order of 10^9 cm. per sec., and, since they do not have to travel many centimetres in pure uranium 235 before they produce new fissions, the time between successive generations is of the order of 10^{-8} second. Thus in less than a millionth of a second a considerable fraction of the mass of 235 will have undergone fission. A large amount of energy is thus suddenly liberated, raising the temperature of the mass of material to many millions of degrees and the pressure to many millions of atmospheres. The sudden expansion of the hot gases produces a very violent explosion.

For the purposes of the peaceful applications of atomic energy it is obviously necessary to control the chain reaction so that the energy can be released continuously and at a predetermined rate. It would seem at first sight that the control of a reaction which can develop so rapidly and in doing so liberates such enormous amounts of energy must be exceedingly difficult. This is fortunately not the case, and in practice control is a relatively simple matter.

Control depends on the regulation of the flux of neutrons in the reacting system so that at a predetermined level the flux remains constant, only exactly as many neutrons causing fission in one generation as in the previous generation. The surplus neutrons which are produced in the fissions are removed and made unavailable for carrying on the reaction. The reaction will then proceed at a constant rate. This balance of the neutron flux can be achieved either by allowing the excess neutrons to escape or by capturing them in some absorbing material.

If the description I have given of the fission process were quite accurate, this balance of the neutron flux would be exceedingly delicate and control of the reaction would be very difficult. Briefly, the reason for this is that the neutrons have such high speeds—even those we call slow neutrons—that the time between successive generations cannot be made longer than a very small fraction of a second, while any control mechanisms will take a time of the order of a second to act. Thus, if a balanced reaction *could* be achieved, a slight temperature change or mechanical disturbance might affect the balance and cause the neutron intensity to rise at an uncontrollable rate, resulting in a violent explosion.

The fact is, however, that not quite all the neutrons which are liberated in the fission process are emitted instantaneously. Some of the fission products transform after a time with the emission of a β-particle into nuclei which are so unstable that they emit neutrons. Thus the total neutron emission consists of the "prompt" neutrons emitted in the fission process itself and the "delayed" neutrons from some of the fission products, liberated on the average a few seconds after the fission.

Although these delayed neutrons form only a very small fraction of the total neutron emission they have a profound effect on the problem of control, for they can be used to reduce the rate at which the chain reaction develops. This is done in the following way: The assembly of fissile material is arranged to be only a very small degree above the critical size, so that the prompt neutrons alone cannot maintain the reaction but need the help of the delayed neutrons. Thus each generation of neutrons has to wait for the delayed neutron emission before a sufficient increase in intensity can occur to keep the reaction going. The rate at which the neutron level can rise is limited by the delay, on the average a few seconds, and is therefore quite slow. The control devices are thus given time in which to act and to take charge, and to hold the neutron intensity and the level of the reaction at any desired value.

THE GRAPHITE PILE

Earlier in this lecture I said that natural uranium is unable by itself to sustain a chain reaction, no matter how large the block of metal is made. This is because the abundant isotope 238 can capture neutrons without undergoing fission and because it undergoes fission only by very fast neutrons. It thus removes neutrons without contributing enough to replace them, and, since this isotope is 140 times more abundant than the 235 isotope, the effect is to prohibit the reaction.

This difficulty could be overcome by reducing the proportion of the 238 isotope—that is, by a process of isotope separation. Although no large reduction would be required the process would be very difficult and very costly.

A simpler and more economical way is to make use of the fact that slow neutrons are much more effective in producing fission in 235 than are fast neutrons. Slow neutrons are also more easily captured by the 238, and so there is still a strong competition between the 235 and 238, but, provided the neutrons can be made to move slowly enough, the chain reaction becomes possible with ordinary uranium.

The neutrons are emitted in the fission process with speeds of the order of 10^9 cm. per sec. They can be slowed down by causing them to make collisions with light atoms, such as hydrogen, deuterium, helium, carbon, &c. In each collision some of the energy of motion of the neutron is transferred to the atom with which it has collided. The neutron is slowed down in a series of steps. The slowing-down process, or moderation as it is called, cannot continue indefinitely since the atoms of the material in which the collisions take place, the moderator, are themselves in motion by reason of their thermal agitation. The process of slowing down can only proceed as far as the stage when the energy of the neutrons is on the average equal to the energy of thermal agitation of the atoms of the moderator. At normal temperature the average speed of the neutrons will then be about 2 km. per sec. This stage will be reached more quickly the lighter the atom of the moderator, so that hydrogen will be the most effective material, with deuterium next, and so on.

There is, of course, the possibility that the moderator itself may capture neutrons, and this limits the choice of moderator; also very considerable amounts of moderator are required.

Only two materials have so far been successfully used—deuterium in the form of heavy water, and carbon in the form of graphite. Heavy water has some advantages, but it is very expensive, whereas graphite is relatively cheap and abundant. Graphite is therefore the most convenient material to use as the moderator.

Owing to the inevitable, though small, loss of neutrons by absorption in the graphite the working margin is small; the competition of the uranium 238 is so severe that there are few neutrons to spare. It is therefore necessary to keep down the loss of neutrons by leakage, which implies a rather large critical size of the reacting system, so that some tons of uranium and of graphite are required.

For reasons depending on the nuclear properties of uranium, the most effective arrangement of the uranium and the graphite is one in which lumps of metallic uranium are disposed at regular intervals throughout a large block of graphite. The best size of the uranium lumps and of the spacing can be calculated from the nuclear constants of the materials.

In practice it is necessary to arrange for a coolant to be circulated around the uranium lumps in order to remove the heat generated by fission, and it may on occasion be necessary to replace the uranium without disturbing the assembly of the pile. For these reasons the arrangement used is a rod lattice of cylindrical symmetry, in which short rods or slugs of uranium are loaded in horizontal cylindrical channels in the graphite block.

If a uranium 235 nucleus in one of the uranium rods undergoes fission the neutrons liberated in the fission will in general fly out of the rod into the graphite, where they are gradually slowed down, wander around, and finally enter another rod of uranium. There they will either produce fission in an atom of uranium 235 or be captured by a uranium 238 nucleus, with the former process slightly predominating. The energy of the fission fragments will be converted into heat in the uranium metal rods and there will be a flux of neutrons and γ-radiation throughout the pile, with an intensity proportional to the rate of the chain reaction or the power level at which the pile is operating.

The essence of control is to make the assembly of uranium and graphite only a very small degree above the critical size. The chain reaction can then only be maintained by the contribution of the delayed neutrons, and the rate at which the neutron level can change is very slow.

The reaction can then be controlled by pushing into or pulling out of the pile control rods made of cadmium or boron. These substances absorb slow neutrons very strongly, so that a small movement of the control rod by means of a simple mechanical device will suffice to regulate the reaction. These controls can be connected with instruments which measure the neutron density in the pile and thus the power level, and in this way the pile can be kept automatically at a predetermined level.

The power level of a pile is limited only by the rate at which the heat can be removed and by the physical and chemical properties of the materials. As the power increases the temperature of the uranium rods rises and the safe limit of this temperature fixes the maximum power at which the pile can be run. Since uranium oxidises rather easily the rods must be clad with a protecting jacket of aluminium if more than a very small power is required. Even then high temperatures cannot be reached, on account of corrosion of the aluminium. If very high powers are desired, as in the piles for the production of plutonium, the cooling must be very effective, and in these piles a very large circulation of water is used to remove the heat rapidly. For piles of moderate power, however, sufficient cooling can be obtained by pulling or blowing air through the channels in which the uranium rods are placed. In this way a power of a few thousand kilowatts can be achieved and this is enough for most research purposes, including the applications to biology and medicine which I shall shortly describe.

The neutron and γ-radiation intensities inside a pile operating at a few thousand kw. are very high. The γ-radiation alone is equivalent to the radiation from a few tons of radium. Most of this radiation will be absorbed in the pile itself, but the fraction which escapes would still be very dangerous to human life. It is therefore necessary to enclose the pile within thick concrete walls.

MEDICAL APPLICATIONS OF THE PILE

The chief purpose for which the graphite pile has been used so far has been the manufacture of plutonium. When uranium 238 captures a neutron an unstable isotope of mass 239 is formed which passes through two successive β-transformations and turns into plutonium. This is an easily fissile material which can be used to make atomic energy reactors, either bombs or controlled reactors.

The plutonium has to be separated chemically from the uranium, a troublesome operation owing to the intensity of the radiations emitted by the fission products and on account of the large amounts of material which have to be handled.

To produce the quantities of plutonium which are needed to make reactors, a large graphite pile dissipating some hundreds of thousands of kilowatts is required. Owing to the difficulties in removing such a large amount of heat from a system of this kind the construction of these large piles is a formidable operation.

A much smaller pile, say of a few thousand kilowatts, of the air-cooled type, is sufficient for all general scientific purposes, including the applications to medicine and biology. Such a pile can make only a gramme or two of plutonium a day, a quantity of no military significance. It is thus possible to pursue some of the peaceful applications of atomic energy without at the same time setting up a plant to produce weapons of destruction. The medical applications in particular belong to the category of what we may call the "safe" developments of atomic energy.

There are various ways in which the graphite pile can be used in medicine and biology, not all of equal importance.

(1) The pile as *a source of neutrons and gamma-radiation.* By making a channel in the concrete wall enclosing the pile, a beam of neutrons and γ-rays can be allowed to escape. This beam can be used for experimental purposes, both physical and medical, but it has probably very little therapeutic value. The neutrons in the beam are mostly of low energy; and such experience as we have on the relative efficiencies of neutrons and X rays in the treatment of malignant tumours has not indicated that neutron therapy has any advantages.

(2) The pile can be used for *the production of radioactive substances.* These are produced in two ways.

First, the two fragments into which the uranium nucleus divides are radioactive and undergo transformation into further active elements, sometimes a whole series of transformations taking place. The fission itself occurs in a variety of ways, so that as a result of a large number of fission processes a wide variety of radioactive isotopes is produced, from zinc to the heavier rare earth, with the majority in the region of barium and strontium. The amounts of material, measured by their radioactivity, which can be produced in this way are very large indeed, so large that it may not be practicable to deal with the main bulk.

Secondly, radioactive isotopes can be produced in the pile because it is a copious source of neutrons. The pile is so constructed that there will be more neutrons than are required to maintain the chain reaction, the surplus neutrons being removed by the control rods. Part of the function of the control rods can be assumed by substances inserted in the pile, which, by absorbing some of the surplus neutrons, form radioactive substances. In this way radioactive isotopes of nearly all the elements can be made. (The number known at present is about 450.) The amounts of the substances produced in this way depend on the number of surplus neutrons available, the power level of the pile, the amount of the bombarded material which is inserted, and its reactivity to neutrons.

This second method of producing radioactive substances is similar to the use of a cyclotron for the same purpose. It is, however, more restricted, for the cyclotron can provide a greater diversity of bombarding particles—protons, deuterons, and α-particles as well as neutrons—while the pile is a source of neutrons only. Even these are mostly of low energy, so that large yields can be obtained only in cases where the substances are made by means of a neutron capture process, the (n, p) and (n, γ) processes. On the other hand, the flux of neutrons is so intense that the yields are, on the average, at least a thousand times greater than with the largest cyclotron.

USES IN RADIOTHERAPY

These radioactive substances can be used as sources of radiation in radiotherapy, as an alternative to radium and radon both in beam therapy and in interstitial and intracavitary therapy.

The pile can produce some hundreds of curies per day of mixed fission products. If these were separated from the uranium metal in which they are formed, highly concentrated sources of radiation could be prepared which would be very suitable to replace radium in teleradium therapy. Alternatively, small blocks of uranium metal could be irradiated in the pile and used without separation; in this case the preparation is easy, and the dangerous and costly separation process is avoided, but the source will not be so concentrated.

At least two other materials which can be prepared in sufficient quantity—cobalt 60 and tantalum 182—would be suitable as sources of γ-radiation and substitutes for radium in beam therapy. For interstitial and intracavitary therapy, several other radio-elements would be satisfactory substitutes for radium or radon.

A single pile of a few thousand kilowatts should be able to produce sufficient material to treat at least 10,000 cases a year and in addition to maintain several large beam units for teleradium therapy. It should thus provide all requirements for radium therapy in this country.

SELECTIVE IRRADIATION

Next, the radioactive substances can be used for selective irradiation of cells and tissues, depending on the selective absorption of suitable radioactive isotopes in specific cells and tissues. In such cases the chemical and physiological properties of the substance are of first importance, since these determine the selective absorption in the tissues which it is desired to irradiate. Further, a radioactive isotope which emits β-rays of low energy will in general be desirable, in order to limit the action to those specific tissues or cells.

So far only two radioactive isotopes have been proved to be useful therapeutically—phosphorus and iodine.

Radiophosphorus has proved very effective in the treatment of polycythæmia and useful in the treatment of myelogenous leukæmia.

In polycythæmia doses of 2–4 mc. of radiophosphorus have caused the disappearance of the symptoms. The patient is enormously relieved and the remission may last for two years without further treatment.

In the case of myelogenous leukæmia, among some 150 patients treated with radiophosphorus the results were fairly good. The growth of the cancer cells is restrained to some extent and the symptoms are lessened, but life is prolonged by no more than a few months at most. The use of radiophosphorus has one advantage over the conventional X-ray treatment in that there is less radiation sickness involved; on the other hand there is some difficulty in arriving at the correct dose, with an indefinite hazard from the effects of the radiations.

In lymphatic leukæmia there seems to be no advantage whatever in the use of radiophosphorus.

Radio-iodine has been shown to be effective in the treatment of overactivity of the thyroid and of a particular but rather unusual form of thyroid cancer.

Because of the great avidity of the thyroid for iodine, especially when overactive, it is possible to place the radiation directly inside the cells which it is desired to irradiate. About 50 cases of hyperthyroidism have been treated with radio-iodine and in 40 of these the disorder was controlled. Some patients who had not responded to other forms of treatment responded well to radio-iodine. The duration of the remission has not yet been established and it is not certain that there may not be untoward after-effects from the radiation. It seems possible, however, that treatment with radio-iodine may possess some advantages over other forms of treatment, and it is worthy of extended experiment.

Some attempts have been made to treat cases of thyroid cancer with radio-iodine, and in one or two cases of an unusual form of cancer a pronounced effect was obtained. In the more malignant forms, however, there was no evidence of any benefit. In fact only a small fraction of thyroid cancers pick up iodine preferentially and the more malignant the tumour the less is the possibility of affecting it by means of radio-iodine.

On the whole the results of this new method of selective irradiation may appear somewhat disappointing. Such success as has so far been achieved is mainly with relatively benign diseases which respond to the normal methods of treatment. We must remember, however, that this new method is in its infancy and that its development and scope have been limited. Progress is likely to be slow and it would not be reasonable to expect immediate success.

TRACERS

The most promising medical application of these radioactive substances lies in the investigation of the fundamental chemical processes of the body through their use as "tracers."

Nearly all the ordinary chemical elements can now be obtained in radioactive modifications. These have exactly the same chemical properties as the usual forms, so that if a radio-isotope is mixed with a sample of the same element it will accompany the stable form through any series of chemical processes, however complicated these may be, and it can always be recognised by its radioactivity. The radioactivity acts as a label enabling us to detect the presence of a particular group of atoms and to follow this group throughout the chemical processes. Thus if we wish to study the distribution of a certain element in a series of biological processes we can mix with it a radio-isotope and we can then follow the distribution by means of the radioactivity.

The use of radio-isotopes also largely increases the sensitivity of the methods of detection and estimation. This may be an important advantage in such cases as the metabolism of very toxic metals or drugs, where an amount of the material sufficient to permit detection by chemical means in specific tissues may cause alterations in physiology or even death.

The radioactivity also permits us to detect the element at a distance so that the samples need not be specially purified and in some cases need not be removed from the experimental animal. It may also in some circumstances permit a continuous examination of the accumulation of material in an organ without interfering in any way with its normal functioning.

In short, the use of radioactive tracers does not merely supplement the direct chemical approach to the problems of metabolism but it opens up new possibilities in clarifying and analysing their most intimate details.

The first attempt to apply these methods was made by Hevesy in 1923, when he used a radioactive isotope of lead to investigate the metabolism of that element in plants. At that time, however, only the naturally occurring radio-elements were obtainable, none of which are normal constituents of biological systems. The technique was therefore very limited in its application. It was not until the discovery of artificial radioactivity in 1933 and the development of the cyclotron that radio-isotopes of the common elements became available, providing this new and powerful method of research for the biologist. The first to use it were Chiewitz and Hevesy in 1935, who investigated the metabolism of phosphorus in rats, using radiophosphorus as a tracer. Since that time the method has been applied in nearly all the biological sciences and much new and significant information has been secured, some of which could have been acquired by none of the former methods.

There are three general ways in which the tracer technique has been applied.

(1) *By Examining Samples.*—The technique most widely used, and one which is applicable to all radio-elements, is to follow the distribution in the tissue by quantitative measurement of the radioactivity in samples of the tissues after removal from the body. Thus radiophosphorus may be mixed with inactive phosphorus and converted into sodium phosphate, which is then administered, mixed with the food or as a subcutaneous injection, to a rat. After the lapse of an appropriate time the rat is killed and the various organs and tissues removed. The amount of the administered phosphorus which has reached the various tissues can now be found by a simple measurement of the radioactivity.

Further, the conversion of the administered phosphorus into various complex organic compounds by the physiological processes of the body may be observed. Here the compound must be isolated from the tissues and its radioactivity measured. In this way the rôle of phosphorus in metabolism has been studied in considerable detail. It has been possible to estimate how much finds its way to the different parts of the body, such as the bones, teeth, liver, kidneys, &c., how long it takes to arrive there and by what path, how long it stays, and so on.

The rate of conversion to cephalin and lecithin, the formation of phosphatides in livers, the origin of milk phosphorus, the synthesis of hæmoglobin from iron, of thyroxine and diiodotyrosine from iodine, and many similar questions have been studied by this means.

The method is, of course, not restricted to the administration of simple inorganic compounds. Complex organic compounds can be labelled by including radio-elements in their molecules. Thus thiamine (vitamin B_1) has been labelled by synthesising it from radiosulphur, and its fate in the body has been followed by measuring the distribution of the radiosulphur in the various tissues.

(2) *By Direct Measurement of Radioactivity.*—If the radio-isotope emits penetrating γ-rays its presence can be detected through several centimetres of tissue. The presence in a particular organ can then be detected by placing a Geiger-Müller counter over the organ and measuring the intensity of the γ-radiation. This technique has been used to observe the selective absorption of iodine by the thyroid and the circulation of the blood, using radiosodium as a tracer.

An extensive study of the iodine metabolism of the thyroid gland in both normal and goitrous human beings has been made by this method. The deposition of the administered iodine in the thyroid is measured with a Geiger-Müller counter placed against the subject's neck. In this way the patient is not disturbed by any surgical treatment and the changes in the amount of radio-iodine in the thyroid can be followed over a considerable period.

Experiments by Hamilton and Soley, by Hertz, and others showed that thyroids of patients with thyrotoxicosis accumulate and retain a large proportion of the administered radio-iodine, that the thyroid tissue can be destroyed selectively by the irradiation of the radio-iodine without apparent damage to the other tissues of the body, and that the iodine is deposited preferentially in the regions of the thyroid tissue which are the most hyperplastic.

(3) *By Photography.*—A third method of observation makes use of the photographic action of the radiations from the radio-isotope. Thin sections of the tissue under investigation are placed against photographic films. After an adequate interval the films are developed and will show areas of darkening corresponding to the regions of the tissue in which the radio-isotope has been deposited. The sections are stained and each section is compared under the microscope with its corresponding film. In this way a correlation can be established between the histological structure of the tissue and the deposition of the labelled element. This method of observation is more qualitative than the others, but it has certain advantages in addition to its simplicity.

ILLUSTRATIVE USES OF RADIO-ISOTOPES

I wish now to give some examples of the use of radio-isotopes in the solution of certain problems.

(1) *Permeability of Membrane of Red Cell.*—In human beings the concentration of sodium ions in the blood plasma is about twenty times that inside the red cell, while the potassium concentration inside the cell is about twenty times that in the plasma. Although potassium and sodium ions behave in much the same way chemically, and although there are well-marked changes in the concentrations of chloride and bicarbonate ions during the cycle of respiration, so that the membrane of the cell is clearly permeable to these, this peculiar difference is maintained. To explain this behaviour it has generally been supposed that the membrane of the red cell possesses a selective impermeability to the positively charged basic kations, so that once a cell was born with its peculiar sodium and potassium concentrations it could maintain these concentrations against the very different concentrations in the blood plasma by not exchanging across the surface of the membrane.

This problem was attacked by Cohn by means of the tracer technique. A small amount of labelled sodium chloride, too small to raise the sodium concentration appreciably, was injected and in some minutes it was distributed uniformly throughout the blood. Samples of blood were then drawn from time to time so that any penetration of radiosodium into the red cells could be measured. It was found that penetration did in fact take place and that eventually the concentration of radiosodium in the red cells and in the plasma assumed the normal ratio. Similar results were obtained with radiopotassium. This proved conclusively that there is a continuous exchange of kations through the membrane of the red cell, and that some mechanism other than impermeability must be present in order to preserve the difference in concentrations.

(2) *Effect of X Rays on Cellular Division.*—The preliminary stages of mitosis involve the transfer of nucleotides from the cytoplasm to the chromosomes, their conversion from ribose into desoxyribose nucleotides, and their polymerisation into long chains. At the end of each mitosis the nucleotides are surrendered by the chromosomes. Thus there is a cyclical chemical process.

It is well known that radiation by X rays inhibits cell division in growing tissues and therefore influences their chemical changes at some stage. In remarkable contrast, full-grown tissue is hardly affected by moderate doses of X radiation. Hevesy has studied this question by determining the rate of formation of the desoxyribose nucleic acid before and after irradiation by X rays, using radiophosphorus as an indicator. He found that X rays inhibited the formation of desoxyribose nucleic acid not only in growing tissues but also in full-grown tissues, and to about the same extent in each. The greater part of the inhibiting action disappears in a hours after the irradiation.

Hevesy's results explained the difference in the of X rays on growing and full-grown tissue (the grown tissue has time to recover) and suggested important clues to the sensitivity of tissue to X and to some difficulties in the treatment of by radiation.

(3) *Blood-transfusion.*—Some interesting examples the tracer technique are afforded by work carried in the United States during the war in studies of su shock and in the development of methods for preservation of whole blood for transfusion.

In this work the radio-element used was radio-iron, since iron is a constituent of hæmoglobin. Two radio-isotopes of iron are known—Fe^{55} which has a half-life of 4 years, and Fe^{59} which has a half-life of 44 days. Because of the difference in the rates at which they lose their radioactivity it is easy to distinguish one of these types from the other.

In the experiments on blood-transfusion one of these radio-isotopes of iron was injected into the recipient of the blood-transfusion, thus labelling his red corpuscles, and the other type of radio-iron was injected into the blood-donor, so as to label the red corpuscles of the blood used for transfusion. This device enabled several important investigations to be carried out concerning the interaction of blood types, which have clarified some points in blood-transfusion and have applications in obstetrics as well as in surgery.

A very important contribution of this technique was the determination of the best methods for the preservation of whole blood and for setting up the technical standards for the blood-donor programme in the U.S.A. By this device of labelling the red corpuscles of the donor's blood direct evidence was obtained on the potency of this blood after various durations of storage when admixed with various suggested preservatives. At the end of any given storage period the blood was transfused into a recipient and shortly afterwards the amount of the donor's blood which still remained active in the recipient's blood-stream was determined by measurement of the radio-iron. It was by this method that the U.S.A. standards for blood storage were established.

CONCLUSION

These few examples of the applications to medicine and biology of this new technique of investigation will perhaps suffice to show its extraordinary delicacy and power and its ability to attack problems which have hitherto been inaccessible to direct experiment. It can hardly be questioned that the development and wider use of this technique will bring rapid and remarkable progress in our knowledge of the fundamental chemical processes in the body and in our knowledge of health and disease.

To derive the full benefit from this new method we must have ample supplies of these radioactive materials. Many of them, and all those which are isotopes of the chemical elements directly concerned in body metabolism, can be made by means of a cyclotron. But the quantities which can be made in this way are relatively small. An atomic pile, because of its more copious supply of neutrons, will in general make far larger quantities—of the order of a thousand times more than can be made by a large cyclotron. Thus a single pile of moderate power would be able to supply all the tracer elements needed in this country. Such a pile has no direct military application, it has no significance for the production of atomic bombs, for its rate of manufacture of plutonium is too small. It is essentially a "safe" development of atomic energy and one which, by enabling us to discover more, and more quickly, about the human body, may bring untold benefits in its train.

ADDED INFECTIONS IN BURNS

A STUDY OF 233 CASES

LEONARD COLEBROOK
F.R.C.O.G., F.R.S.
MEMBER OF SCIENTIFIC STAFF, MEDICAL RESEARCH COUNCIL

JOHN M. DUNCAN * W. J. H. BUTTERFIELD
M.B. Birm. B.M. Oxfd

From the Birmingham Accident Hospital

Bourdillon and Colebrook (1946) described a first attempt to keep burns uninfected by dressing them in a dust-free atmosphere, along with other precautions. They analysed the few added infections that took place during the first twelve months of this régime, and concluded that, in more than 1400 dressings, neither hæmolytic streptococcus nor *Ps. pyocyanea* was transmitted in the course of dressing from any patient to another.

A few added infections with these organisms and with *B. proteus* did take place, but the evidence seemed to point clearly to transmission at some other time than during the dressing. It was suggested that such transmission might easily happen in the wards if the covering of the burns became imperfect at any time, or if the patient interfered with it.

In some situations—e.g., the face, and the buttocks near the perineum—it is manifestly impossible to secure and maintain complete covering. In children the neck, chin, and shoulders, which are often accidentally scalded, are notoriously difficult to seal off effectively with dressings, especially after the children have recovered from the early shock and cannot be kept still.

We report here a further study of infection acquired apart from dressing the wound. The investigation overlaps that reported by Bourdillon and Colebrook (1946) and deals with the twelve months August 1, 1945–August 1, 1946, during which we always recorded, when we started a dressing, whether the wound still had perfect or imperfect cover, or had been exposed at any time since the last dressing. The records, illustrating the importance of cover in relation to site of burn, were as follows:

Site	*Perfect cover*	*Imperfect cover*	*Total*
Limbs	770	96 (11%)	866
Trunk	123	80 (40%)	203
Buttocks	29	77 (72%)	106
Face and neck	69	54 (44%)	123

Our daily records also show the order in which patients are dressed and the clinical condition and bacteriological flora of each burnt area at the time of its dressing. All these data taken together enable us to decide, with a considerable degree of probability, whether any particular lesion acquired its added infection at the time of dressing, or between one dressing and the next—i.e., in the ward.

The organisms we have used as indicators of added infection are hæmolytic streptococci, *Ps. pyocyanea*, and *B. proteus*, partly because they are easily recognised in culture and, in the case of hæmolytic streptococci at least, because strains can often be identified by their serological reactions. They were chosen as indicators also because of the strong impression (in the case of hæmolytic streptococci it may be said to be a certainty) that these three organisms are more often associated with delayed healing and with unsuccessful grafting operations than are most of the other organisms commonly found on granulating surfaces.

Added infections (or contaminations) with other organisms, especially *Staph. aureus*, have taken place during this period—indeed they have been very common—but up to now we have made no serious attempt to trace the source from which they are transmitted to the burns. Such a task is likely to be very difficult.

METHODS

Bacteriological Examinations.—Swabs from the wounds have been planted, usually within two or three hours, on plates of 5% horse blood-agar, and on plates of 1% 'Cetavlon' agar (Harper and Cawston 1945). These plates were incubated only aerobically, owing to difficulties of supply and labour. When *B. proteus* was known to be present or was suspected, swabs were planted by Cawston's modification of the Fry method (Colebrook et al. 1945) and by the more recent method of Pearce (1946).

Dressings have been carried out as described by Bourdillon and Colebrook (1946). In most cases, except when it was almost healed, the burn was covered with tulle gras (with or without penicillin cream under it), then dry sterile gauze, then absorbent wool, extending well beyond the gauze, and finally crêpe bandages. The bandages have been held in place whenever necessary with strips of strapping or, in many cases, if there was any likelihood of interference with the dressing by the patient's fingers, with a light shell of plaster-of-paris. Burns of the face, if not severe, were sometimes left without dressings, being only smeared with penicillin cream from time to time.

ADDED INFECTIONS AND THEIR PROBABLE SOURCES

The term "added infection" is used to denote the growth of one of the three indicator organisms from a burnt area of a patient who had been free from such infection on admission, such organisms being obtained at any time during the patient's stay in hospital.

Bourdillon and Colebrook (1946) described the principles which guided them in deciding whether each added infection was or was not probably acquired in the dressing-station. The same considerations apply to the data given below, but our evidence is somewhat more complete, our records showing whether the burnt areas were imperfectly covered, and therefore liable to infection from without, when their added infections were first detected.

Between August 1, 1945, and August 1, 1946, 233 cases were admitted, almost half of them children. The burns of 13 cases were already infected on admission with one or other of the three indicator organisms—9 of them with hæmolytic streptococcus. During this period no dressings have been carried out in the open wards. All first dressings (of fresh burns) were done either in the plenary treatment room or in the shock room, neither of which is supplied with dust-free air. All the subsequent 1419 dressings were done in the dust-free atmosphere of the dressing-station, except 107 in the saline bathroom, which is not air-conditioned.

Streptococcus hæmolyticus has been responsible for added infection in 12 patients (5%) after admission. Only 2 of the 12 had extensive burns; 1 of them acquired her streptococcus after eight weeks, and it had no clinical ill effects. The other patient acquired her streptococcus during the eleventh week of her recovery and lost it within three days. This took place during a phase of breakdown of her grafted areas, which seemed to be due to an acquired sensitivity to tulle gras. In none of the remaining 10 patients was the arrival of hæmolytic streptococcus on the burns associated with any signs of acute sepsis, and in none did the organism persist more than a few days. It may be said, therefore, that, among the whole 224 patients admitted without streptococcal infection during the period, the clinical effects of added infection with that organism have been practically nil. Of the 12 patients with such added infections, 3 had never been in the dressing-station and 9 had not followed a streptococcus-infected case in the dressing-station at the last dressing. One patient did follow a streptococcus-infected patient in the dressing-station, but the infected lesion (a finger) had been exposed in the ward, where there was another streptococcus-infected patient; *hence it is doubtful where the infection took* place. We conclude that 11 of the 12 certainly, or very probably, acquired their streptococci outside the dressing-station. The burnt areas of 8 of these are known to have had imperfect cover immediately before their added infection was detected; 6 were anatomically difficult to keep perfectly covered, being burns of neck, chest, buttocks, or thighs.

---

* Receiving a part-time grant from the Medical Research Council.

Ps. pyocyanea was responsible for added infection in 9 patients (4%). In most of them the infection persisted for days or weeks, and we were unsuccessful in eliminating it by any local applications, including proflavine and 'Phenoxetol.' Apart from some possible delay in healing, the infections appeared to produce little clinical effect. None of the 9 patients had followed a pyocyaneus-infected patient in the dressing-station at the last dressing. It is therefore certain, or very probable, that all acquired their infection outside the dressing-station. The burnt areas of 5 of the 9 patients were imperfectly covered immediately before their added infection was detected. One other patient was ambulant and had visited a patient admitted with pyocyaneus.

B. proteus was responsible for added infection in 14 patients (6%). Of these 14 patients, 4 had never been in the dressing-station and the remaining 10 had not followed a proteus-infected patient in the dressing-station at the last dressing. All of them, therefore, had certainly, or very probably, acquired their infection outside the dressing-station. The burnt areas of all of the patients were imperfectly covered immediately before their infection was detected, and 11 were so situated as to be difficult to cover adequately (buttocks, chin, neck, &c.).

Summing up these data, of the 220 patients whose burns were free from all the three indicator organisms on admission, 29 (13·2%) acquired one or more of them at some time during their stay in hospital. Of these 29 patients, 14 were children under 5 years of age and 4 were older children. (Of the 29 patients, 5 acquired more than one of the three indicator organisms.) In only one instance was there reason to suspect that the infection may have been transmitted at the time of dressing in the dressing-station. In all the other cases it probably took place in the ward in the interval between dressings.

It is evident, too, that the risk of added infection has been closely related to success or failure in keeping burnt areas adequately covered with dressings. Further evidence on this point is provided by the fact that, out of 1104 dressings of areas recorded as having perfect cover when they arrived in the dressing-station, only 9 (0·8%) acquired an added infection with one of the three indicator organisms; whereas among 315 dressings of areas recorded as having imperfect cover, 27 (8·6%) acquired an added infection.

The exact source of all these added infections is not evident. It is conceivable that a few of them may have been due to transfer of the organism from the patient's skin or from some other part of the patient's body—e.g., the respiratory, alimentary, and urinary tracts. It is unlikely that such transmission was common, in view of the following facts. Hæmolytic streptococci were not isolated from throat swabs of 7 of the patients who acquired an infection of their burns with that organism (only 2 patients had a positive swab, and 3 were not swabbed). And these streptococci are rarely found on the skin or in the fæces of normal persons (Colebrook et al. 1935, Hare and Maxted 1935). Pyocyaneus and proteus are still more rare in the throat and on the skin. Both may be found in pathological conditions in the bowel or in the urinary tract, but they are rarely found in normal persons. It seems very probable, therefore, that most of the added infections in our patients have arisen by transfer of infective material in some way from a source outside the patient.

We know that clouds of organisms, often including potential pathogens, are liberated whenever bedding is shaken, and therefore also during the routine process of bed-making (Bourdillon and Colebrook 1946, Willits and Hare 1941). In this connexion it should be remembered that most hospital laundries do not a to sterilise blankets (Colebrook et al. 1945). A and often larger scatter of organisms into the air place whenever dressings are applied (Bourdillon Colebrook 1946). Pathogens must also be intro sometimes on the clothing of doctors, nurses, and visito especially when these are throat- or nose-carriers streptococci (Willits and Hare 1941); and they are carried by flies (Shooter and Waterworth 1944) and by drinking-utensils, bedpans, and thermometers, if t are not sterilised. The interchange of fluffy toys, or materials used for occupational therapy, constitutes another possible pathway for infection which is sometimes overlooked.

PREVENTION OF ADDED INFECTIONS IN THE WARDS

No single remedy is likely to secure a high degree of immunity from these infections. The following procedures have seemed to us of chief importance:

1. Maintenance of perfect cover.
2. Restraint of bacterial growth on the burnt surfaces, and rapid elimination of reservoirs of infection.
3. Rapid restoration of the epithelial covering by early and repeated grafting.
4. Anti-dust measures and elimination of flies.
5. Segregation of infected cases in cubicles.
6. Routine purification of the air of the wards.

(1) *Maintenance of Perfect Cover.*—The close connexion which has been shown between the incidence of added infection and the adequate covering of the burns makes it obvious that continuous attention to this detail is all important. Our practice has been to cover the whole of the burnt area with sterile gauze extending beyond the limit of the lesion and, over this in turn, to apply wool about $^3/_4$–1 in. thick, extending well beyond the gauze, to avoid infection from without, like the wool plug of the bacteriologist's test-tube. The whole dressing is then secured with crêpe bandages, which again extend well beyond the wool. We emphasise the necessity for these bandages in dealing with burns dressed at infrequent intervals (5–10 days). Admittedly they are expensive, but not unduly so if they are washed and repeatedly resterilised. Economy in bandages can be easily offset by a longer stay in hospital.

Finally, to defeat the patient who is likely to jump about in bed and cause his bandages to work loose, we often fix the bandages with long strips of strapping carried on to the unburnt skin or, still more effectively, with a thin shell of plaster-of-paris over the crêpe bandages. This last procedure is, in our experience, the only answer to the exploring fingers possessed by so many children.

Some simple rules may be recommended for burns of particular situations:

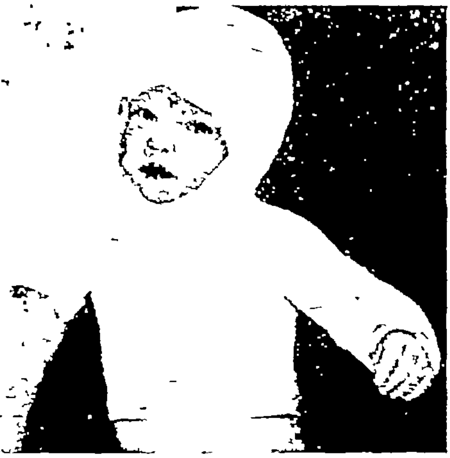
(*a*) For burns of the neck and shoulders (very common in young children and difficult to keep covered) the dressing should extend on to the head and over the chest. For children a plaster-of-paris shell is almost essential (see figure).

(*b*) For burns of the arm, forearm, or leg, bandage from the phalanges to above the elbow or knee joint (with the joints in the correct position for function).

(*c*) For burns of the trunk, bandage the whole trunk and both shoulders. If the burn extends down past the iliac crest, include the appropriate hip. A plaster-of-paris shell is often advisable.

(*d*) For burns of the face, to avoid infection during the first few days before repair has started, and to prevent excessive exudation into the loose tissues, the dressing should cover the whole face except for small apertures giving access to the mouth and nostrils; and firm pressure should be applied over plenty of wool, particularly over the eyes and forehead. After two or three days the eyes may usually be uncovered. This applies only to severe burns of the face. Superficial flash burns can often be treated without dressings if a bacteriostatic cream is applied.

Sandeep



Thin plaster-of-paris shell over crêpe bandages to maintain perfect cover of burns of neck and shoulders in a child.

(e) For burns of the buttocks (common in young children) it has been found helpful to elevate the legs with strapping extension on a gallows frame.

A complete antibacterial barrier having been obtained by these devices, daily careful examination of the bandages during the ward round is essential. Never was the proverb "A stitch in time saves nine" more apposite.

(2) *Restraint of Bacterial Growth on the Burn and Elimination of Reservoirs of Infection.*—Since it has been clearly demonstrated that sensitive organisms—e.g., hæmolytic streptococci—can be rapidly eliminated from superficial lesions, such as burns, with penicillin (Clark et al. 1943) and sulphanilamide (Colebrook and Francis 1941), there can be little doubt that these agents will also check the free outgrowth of many organisms which are somewhat less sensitive—e.g., staphylococci, diphtheroids, coliforms, and non-hæmolytic streptococci. We have therefore used as our routine dressing for the past three years a cream containing penicillin and sulphathiazole in a bland base (Clark et al. 1943); and results have been so satisfactory that we have seen no reason to change it. (The only reservation we make is that an occasional patient becomes hypersensitive to some ingredient in the cream, and for that reason it is undesirable to continue it for more than three or four weeks as a rule.)

After the first application of this routine cream the dressings are left undisturbed for 7–12 days; after subsequent dressings usually for 5–7 days. If on admission or at any subsequent dressing a wound is found to have acquired hæmolytic streptococci, a course of four or five applications of penicillin cream at two-day intervals is instituted. We attach great importance to this practice, since it eliminates reservoirs of hæmolytic streptococci. As the range of our chemotherapeutic attack is expanded to include organisms such as pyocyaneus, proteus, and the coliform bacilli, it will no doubt become possible to reduce considerably the number of added infections.

(3) *Rapid Repair of Epithelial Skin Covering.*—It will always be difficult to keep large granulating surfaces free from added infections for many weeks, and the longer they are not covered with epithelium the more fibrous tissue will be formed beneath them, leading often to serious loss of function. For all these reasons grafting should be carried out as early as possible—sometimes during the first week. And if, as often happens, it does not succeed in completely covering the burnt area it should be repeated without delay. The practice of taking rather more skin than is required at the first grafting operation and storing the unused part in the refrigerator (Mathews 1945) for subsequent use is of the greatest value. Repeated regrafting of unhealed areas with stored skin, or with small grafts obtained under local anæsthesia, should be a routine dressing procedure, not an operation requiring the use of an operating-theatre and an anæsthetist.

(4) *Anti-dust Measures and Elimination of Flies.*—Bed-making is responsible for a large part of the dust in the ward, and the sweeping of floors, if these are not oiled, for its repeated dissemination through the air. By the oiling of blankets after they are laundered (Harwood et al. 1944) and of floors (Andrewes et al. 1940) both these sources of air-borne contamination can be very much reduced. The ward floors in the burns unit have been oiled once in three weeks and, apart from their being a little slippery for a few hours, no inconvenience has been caused by it. The oiling of blankets has not proved difficult, except inasmuch as it involves one additional process for the laundry staff; nor has it required any new apparatus. The oil cannot be detected by touch or smell. No ill effects of its use have been detected, except perhaps some shrinkage of the blankets.

Even in temperate climates flies can be a nuisance in a burns ward during hot weather. There is bound to be a slight odour from the extensively burnt patient, who is only dressed once in 5–10 days, even if the burn remains uninfected. Occasional spraying with 5% D.D.T. in white spirit has been helpful but will not keep the ward entirely free from flies if their breeding-places—e.g., refuse bins—are not sought and systematically dealt with. A muslin canopy should be used over the whole bed of every extensively burnt patient during hot weather, for a single fly can carry infection to or from such a patient. The complete fly-proofing of wards by fitting fine-mesh gauze to windows and doors is hardly necessary in temperate climates, though one single-bed ward might well be so protected for the exceptionally severe burn which is bound to be somewhat smelly while sloughing.

(5) *Segregation of Infected Cases in Cubicles.*—Single-bed wards have not been available to us hitherto, but there is no doubt that they would reduce the risk of transfer of infection by dust. The ideal burns unit would have perhaps half its bed accommodation in single-bed wards—the rest in wards of 2–4 beds. The windows, doors, and fireplaces of cubicles should be so designed as to allow of being easily sealed off for sterilisation with formalin or other vapour.

(6) *Routine Purification of Air of Wards.*—The great scatter of microbe-carrying particles from bed-clothes and dressings (Bourdillon and Colebrook 1946, Hamburger et al. 1944, Willits and Hare 1941) is a fact which cannot be ignored in any attempt to control cross-infection in hospital wards. The peak load of bacteria in the air which accompanies bed-making or surgical dressings can certainly be reduced by dilution with outside air. Even in a large city the bacterial density of the outside air is much less than that of hospital wards (Colebrook 1946). But ventilation by windows is somewhat capricious and may lead to dissemination of dust besides dilution. Much more controlled and potentially effective ventilation is provided by a plenum system such as has been in use for forty years in the wards of the Royal Victoria Hospital, Belfast (Henman and Lea 1903).

Other procedures worthy of serious consideration in this connexion are the introduction of bactericidal mists—e.g., of triethylene glycol—and of lactic acid (Lovelock et al. 1944) after bed-making; or indirect ultraviolet radiation combined with convection currents, as used by Wells et al. (1942) and Wells (1943) in schools in America. The evidence of Puck et al. (1945) showed that, by combination of anti-dust measures with vaporisation of triethylene glycol, the concentration of streptococci in the air of wards housing patients with pharyngitis was greatly reduced. Further experience is required exposed in the ward, where there was another streptococcus-infected patient; hence it is doubtful where the infection took place. We conclude that 11 of the 12 certainly, or very probably, acquired their streptococci outside the dressing-station. The burnt areas of 8 of these are known to have had imperfect cover immediately before their added infection was detected; 6 were anatomically difficult to keep perfectly covered, being burns of neck, chest, buttocks, or thighs.

Ps. pyocyanea was responsible for added infection in 9 patients (4%). In most of them the infection persisted for days or weeks, and we were unsuccessful in eliminating it by any local applications, including proflavine and 'Phenoxetol.' Apart from some possible delay in healing, the infections appeared to produce little clinical effect. None of the 9 patients had followed a pyocyaneus-infected patient in the dressing-station at the last dressing. It is therefore certain, or very probable, that all acquired their infection outside the dressing-station. The burnt areas of 5 of the 9 patients were imperfectly covered immediately before their added infection was detected. One other patient was ambulant and had visited a patient admitted with pyocyaneus.

B. proteus was responsible for added infection in 14 patients (6%). Of these 14 patients, 4 had never been in the dressing-station and the remaining 10 had not followed a proteus-infected patient in the dressing-station at the last dressing. All of them, therefore, had certainly, or very probably, acquired their infection outside the dressing-station. The burnt areas of all of the patients were imperfectly covered immediately before their infection was detected, and 11 were so situated as to be difficult to cover adequately (buttocks, chin, neck, &c.)

Summing up these data, of the 220 patients whose burns were free from all the three indicator organisms on admission, 29 (13·2%) acquired one or more of them at some time during their stay in hospital. Of these 29 patients, 14 were children under 5 years of age and 4 were older children. (Of the 29 patients, 5 acquired more than one of the three indicator organisms.) In only one instance was there reason to suspect that the infection may have been transmitted at the time of dressing in the dressing-station. In all the other cases it probably took place in the ward in the interval between dressings.

It is evident, too, that the risk of added infection has been closely related to success or failure in keeping burnt areas adequately covered with dressings. Further evidence on this point is provided by the fact that, out of 1104 dressings of areas recorded as having perfect cover when they arrived in the dressing-station, only 9 (0·8%) acquired an added infection with one of the three indicator organisms; whereas among 315 dressings of areas recorded as having imperfect cover, 27 (8·6%) acquired an added infection.

The exact source of all these added infections is not evident. It is conceivable that a few of them may have been due to transfer of the organism from the patient's skin or from some other part of the patient's body—e.g., the respiratory, alimentary, and urinary tracts. It is unlikely that such transmission was common, in view of the following facts. Hæmolytic streptococci were not isolated from throat swabs of 7 of the patients who acquired an infection of their burns with that organism (only 2 patients had a positive swab, and 3 were not swabbed). And these streptococci are rarely found on the skin or in the fæces of normal persons (Colebrook et al. 1935, Hare and Maxted 1935). Pyocyaneus and proteus are still more rare in the throat and on the skin. Both may be found in pathological conditions in the bowel or in the urinary tract, but they are rarely found in normal persons. It seems very probable, therefore, that most of the added infections in our patients have arisen by transfer of infective material in some way from a source outside the patient.

We know that clouds of organisms, often including potential pathogens, are liberated whenever bedding is shaken, and therefore also during the routine process of bed-making (Bourdillon and Colebrook 1946, Willits and Hare 1941). In this connexion it should be remembered that most hospital laundries do not to sterilise blankets (Colebrook et al. 1945). A and often larger scatter of organisms into the air place whenever dressings are applied (Bourdillon Colebrook 1946). Pathogens must also be intr sometimes on the clothing of doctors, nurses, and especially when these are throat- or nose-carriers streptococci (Willits and Hare 1941); and they are carried by flies (Shooter and Waterworth 1944) and drinking-utensils, bedpans, and thermometers, if t are not sterilised. The interchange of fluffy toys, materials used for occupational therapy, con another possible pathway for infection which is sometimes overlooked.

PREVENTION OF ADDED INFECTIONS IN THE WARDS

No single remedy is likely to secure a high degree of immunity from these infections. The following procedures have seemed to us of chief importance:

(1) Maintenance of perfect cover.
(2) Restraint of bacterial growth on the burnt surfaces, and rapid elimination of reservoirs of infection.
(3) Rapid restoration of the epithelial covering by early and repeated grafting.
(4) Anti-dust measures and elimination of flies.
(5) Segregation of infected cases in cubicles.
(6) Routine purification of the air of the wards.

(1) *Maintenance of Perfect Cover.*—The close connexion which has been shown between the incidence of added infection and the adequate covering of the burns makes it obvious that continuous attention to this detail is all important. Our practice has been to cover the whole of the burnt area with sterile gauze extending beyond the limit of the lesion and, over this in turn, to apply wool about $^3/_4$–1 in. thick, extending well beyond the gauze, to avoid infection from without, like the wool plug of the bacteriologist's test-tube. The whole dressing is then secured with crêpe bandages, which again extend well beyond the wool. We emphasise the necessity for these bandages in dealing with burns dressed at infrequent intervals (5–10 days). Admittedly they are expensive, but not unduly so if they are washed and repeatedly resterilised. Economy in bandages can be easily offset by a longer stay in hospital.

Finally, to defeat the patient who is likely to jump about in bed and cause his bandages to work loose, we often fix the bandages with long strips of strapping carried on to the unburnt skin or, still more effectively, with a thin shell of plaster-of-paris over the crêpe bandages. This last procedure is, in our experience, the only answer to the exploring fingers possessed by so many children.

Some simple rules may be recommended for burns of particular situations:

(*a*) For burns of the neck and shoulders (very common in young children and difficult to keep covered) the dressing should extend on to the head and over the chest. For children a plaster-of-paris shell is almost essential (see figure).
(*b*) For burns of the arm, forearm, or leg, bandage from the phalanges to above the elbow or knee joint (with the joints in the correct position for function).
(*c*) For burns of the trunk, bandage the whole trunk and both shoulders. If the burn extends down past the iliac crest, include the appropriate hip. A plaster-of-paris shell is often advisable.
(*d*) For burns of the face, to avoid infection during the first few days before repair has started, and to prevent excessive exudation into the loose tissues, the dressing should cover the whole face except for small apertures giving access to the mouth and nostrils; and firm pressure should be applied over plenty of wool, particularly over the eyes and forehead. After two or three days the eyes may usually be uncovered. This applies only to severe burns of the face. Superficial flash burns can often be treated without dressings if a bacteriostatic cream is applied.

greatly improved and the B.P. reduced to 218/102 mm. After a month's therapy her B.P. was 210/110 mm., but a month later it rose again, and two months later it was 240/110 mm. In spite of the return of the B.P. to slightly higher than its previous level, she was emphatic that her headaches were better than they had been for some years. Up to date, nine months since the beginning of treatment, the B.P. varies between 210/100 and 240/110 mm., but her symptomatic relief continues, and she still gets occasional but much less severe headaches. She also remarked that her feet, which had previously been very cold, were much warmer since therapy; no doubt this was due to the vasodilator action of the drug.

CASE 2.—A male caretaker, aged 52, had led an extremely sedentary existence for twenty years because of varicose veins and varicose ulcers. For the last ten years he had had severe headaches and dizziness, and before admission he had been at rest in bed at another hospital for over a month; but this had not relieved the headaches, and he was so giddy when he got up that he could only sit about the ward.

EFFECTS OF POTASSIUM THIOCYANATE ON HYPERTENSIVE DISEASE

Predominant symptoms	Cases	Effect on symptoms				Effect on blood-pressure		
		Complete relief	Much relief	Partial relief	No effect	Permanently reduced	Temporarily reduced	No effect
Headache and giddiness	27	1	21	5	0	0	18	9
Other symptoms—e.g., insomnia and tinnitus	8	0	0	0	8	0	5	3

On examination he had benign hypertension, with a B.P. of 265/150 mm. Hg. He had considerable enlargement of the heart but no evidence of cardiac failure and no evidence of malignant hypertension.

After treatment with potassium thiocyanate to keep the blood-thiocyanate level at 6–8 mg. per 100 c.cm. there was great relief in the attacks of giddiness and in the headaches. This was striking to all observers, for the patient would now help in ward duties and could walk about without giddiness. After a month's treatment the B.P. was reduced to 198/134 mm. A month later, however, it had risen to 210/140 mm., but there was still considerable symptomatic relief. The patient has continued to obtain relief from symptoms over the past six months, although the B.P. has now risen to 230/140 mm.

COMMENTS

These 2 cases are exceptionally good examples of the value of potassium thiocyanate therapy, because in case 1 no period of rest accompanied or preceded the administration of the drug, and in case 2 the previous period of rest had been so extensive and without benefit that there seemed to be little doubt that the relief in symptoms was due to the thiocyanate. In the 25 other cases symptomatic relief continued so long as the optimal blood-level was maintained, but in all cases the fall in B.P. was only temporary.

The dosage was adjusted to keep the blood-thiocyanate level at 6–8 mg. per 100 c.cm. Rather higher levels, up to 15 mg. per 100 c.cm., have been used by other clinicians, but low levels are equally efficacious and safer. The optimal level varies enormously from patient to patient and can be found only by trial and error. The usual procedure was to give 0·2 g. in chloroform water thrice daily for three days, followed by once daily for the remainder of the week; at the end of the week the blood-thiocyanate level was estimated and the dose raised or lowered as seemed necessary. Some patients maintain a satisfactory blood-thiocyanate level on as small a dose as 0·2 g. thrice weekly. This plan has been found to be safer than starting with larger doses and being prepared to reduce them. Weekly estimations of the blood-thiocyanate levels are done for the first month. After this the dose necessary to keep the level correct remains fairly constant, and less frequent blood estimations become necessary, provided there is no indication of any renal disease which may impair excretion.

No toxic symptoms of any sort were encountered in this series, beyond nausea and loss of appetite in one patient in whom the blood-thiocyanate level had risen to 16 mg. per 100 c.cm. and whose symptoms rapidly disappeared after reduction of the dosage. Serious toxic symptoms have, however, been reported (Wald et al. 1939, del Solar et al. 1945), including extreme lassitude, nausea, vomiting, muscular weakness, rashes, thyroid gland enlargement, coma, and death. In all these cases the blood-thiocyanate level had been high. For this reason it is not justifiable to use potassium thiocyanate unless safer measures have failed.

An objection to this form of therapy is that frequent blood examinations are necessary to ensure safety; but this also applies to many other drugs, such as thiouracil, which nevertheless have a place in therapeutics. The technique of blood-thiocyanate estimation is simple and once learnt can be carried out with ease and speed in any small laboratory. The principle is that of colour comparison with a standard of known concentration.

The *technique* (Ravin 1940) is as follows:

Reagents:

(1) 20 % aqueous trichloracetic acid.
(2) Acid ferric nitrate (5 % ferric nitrate in 2·5 % v/v nitric acid).

Colour Standards:

0·567 g. of potassium dichromate with 38·3 g. of cobaltous chloride hexahydrate is dissolved in 500 ml. of distilled water. This is stock, and corresponds to 20 mg. CNS ion per 100 ml. serum. Prepare standards by dilution from the stock, corresponding to 1 to 20 mg. CNS ion per 100 ml., and seal in comparator tubes.

Technique:

In a tube place 2 ml. of distilled water, 1 ml. of serum, and 1 ml. of trichloracetic acid solution. Mix well, stand 10–15 min. and centrifuge or filter until clear. Place 2 ml. of the clear supernatant fluid in a comparator tube and add 0·4 ml. of acid ferric nitrate reagent. Mix well and compare with standards. If very high values are encountered, repeat with 0·5 or 0·25 ml. of serum.

The most exacting part is the preparation of the standard, but Lovibonds have now made a disk for their comparator, and this simplifies the technique and avoids error which might arise from the standard losing its colour.

In cases of malignant hypertension some relief has also been obtained where headache was a troublesome symptom before there was a rise in the blood-urea, but after this stage no benefit was derived from the drug. In one case with papillœdema, however, where the patient was nearly blind (to the extent of being unable to count fingers), there was considerable improvement of vision after thiocyanate treatment was started, but whether this was due to the drug is difficult to decide. The usual course of malignant hypertension, with terminal uræmia or cardiac failure, did not seem to be influenced in any way, but only 10 cases were treated.

CONCLUSION

It was with a somewhat sceptical attitude and some reluctance that I began to use potassium thiocyanate, owing to the many claims in the past for various drugs in the treatment of hypertension. An attempt has been made to define the true value of this drug, chiefly as regards its value in the relief of headache, and 27 cases of benign hypertension were treated in which headache and giddiness were prominent symptoms. Besides these, 8 cases of benign hypertension, presenting with symptoms other than headache and giddiness, and 10 cases of malignant hypertension were treated. The benign cases were selected and restricted to long-standing cases of hypertension with a history of symptoms for some years. Those in which a functional element was suspected were not chosen for treatment.

The conclusion reached is that this drug has a definite but very limited place in the treatment of hypertension and should be restricted to cases in which hypertensive regarding possible harmful effects of such bactericidal vapours on patients exposed to them at intervals over long periods.

Whatever methods are used, the frequent cleaning of the air of wards housing burnt patients must be regarded as a desirable goal. Sanatorium conditions would probably be ideal, both for avoiding infection and for healing.

COMMENT

The problem of controlling added infections of burns with *Staph. aureus* remains untouched. These infections, which are very numerous, may well play a prominent part in the slow healing of burns during the later stages of recovery, and also in the ætiology of the dermatitis which is apt to complicate these later stages. The elimination of added infections of this class is likely to present great difficulties in view of the prevalence of *Staph. aureus* in the air of hospital wards besides on the skin and in the nose of so many normal persons.

SUMMARY AND CONCLUSIONS

During a twelve months' period—involving more than 1400 dressings—cross-infection by hæmolytic streptococci, *Ps. pyocyanea*, and *B. proteus* introduced while dressing burns has been almost entirely eliminated by doing the dressings in a dust-free atmosphere, using a strict aseptic technique and adopting a penicillin-sulphathiazole cream as a routine application.

During the same period a few added infections by these three indicator organisms have occurred (33 in all), but the circumstances in all but one instance make it highly probable that the infections were acquired apart from the act of dressing the burn. Most of these added infections occurred in patients whose burns had been imperfectly covered for a period before they were re-dressed, and it seems likely that dust was the infecting agent in most cases.

The incidence of added infection in burns which were found to be imperfectly covered when they arrived for re-dressing was 10 times as high (8·6%) as that of the burns which had perfect cover throughout the period between dressings (0·8%).

Among the 224 patients admitted without streptococcal infection only 12 (5%) acquired this infection at any time during their stay in hospital; and the clinical effect of these few added infections was practically nil.

This investigation takes no account of added infections with *Staph. aureus*, which are numerous and possibly important in relation to slow healing.

Our thanks are due to Sister A. Magee, and the nurses who have worked with her, for their loyal coöperation ; W. Cawston and A. Hood for most of the laborious bacteriological work ; and Drs. S. D. Elliott and V. D. Allison, of the Central Public Health Laboratory, for invaluable help in typing streptococci.

HYPERTENSIVE HEADACHE
TREATED WITH
POTASSIUM THIOCYANATE

P. J. W. MILLS
M.R.C.P.
PHYSICIAN, E.M.S. LISTER EMERGENCY HOSPITAL, HITCHIN

MANY drugs have been used in hypertensive disease, and nearly all have been abandoned as of little value in controlling either the course or the symptoms. Among them was potassium thiocyanate, which was first used in 1903 by Pauli, but, owing to its toxic effects, was abandoned without a careful study being made of its therapeutic and toxic doses, there being then no known method of estimating it quantitatively in the blood.

Potassium thiocyanate was again tried in America by Barker and others in 1936, and more recently by a few clinical observers in Great Britain. A simple method of estimating the level in the blood-stream has now been devised, so that toxic doses can more easily be avoided. When the blood-levels of the drug are carefully controlled it has been found to be a comparatively safe and valuable remedy for some of the symptoms of benign hypertension.

The mode of action and full range of usefulness of potassium thiocyanate have not yet been fully investigated. It is known to be a normal physiological constituent of the blood and saliva, and therefore one view is that it acts by replacement, the salivary thiocyanate being low in many cases of malignant hypertension. It seems most unlikely, however, that the ætiology of hypertension is so simple as this. Thiocyanate is also a vasodilator, but the symptomatic relief it gives does not correspond to any lowering of the blood-pressure that may occur.

The symptoms which respond most readily to this drug are headache and dizziness. In 27 cases of benign hypertension in which these symptoms were prominent, all the patients experienced striking relief within two weeks of the institution of treatment. The cases were selected with care, and as far as possible those in which there was an overlying functional element were not included, so that symptomatic relief could be more accurately assessed. In cases where different symptoms, such as noises in the head, insomnia, and mental changes, were more prominent the drug was not found to be of any great value beyond what might possibly be attributed to a functional response. In 8 such cases treatment did not bring any benefit. Other observers, however, have thought that some benefit was derived from this drug in all cases (D'Silva and Evans 1944).

The effect on the blood-pressure varied widely. The drug usually caused some lowering of both systolic and diastolic readings after one or two weeks' treatment, but this lowering of the pressure was not maintained, although symptoms continued to be relieved. There seems to be no definite relationship between the lowering of the pressure and the relief of symptoms (see accompanying table).

ILLUSTRATIVE CASE-RECORDS

CASE 1.—A housewife, aged 53, had severe headaches and giddiness daily for seven years, causing severe incapacity. She was sensible and coöperative, and there was no suggestion of a functional element. Blood-pressure (B.P.) was 230/110 mm. Hg, and there was considerable enlargement of the left ventricle. She had been treated for some years with regular doses of phenobarbitone without effect. Examination was otherwise normal. There was no evidence of malignant hypertension.

Since she had an invalid husband to look after it was impracticable for her to be admitted to hospital for a preliminary rest, and therefore she was given potassium thiocyanate as an outpatient and attended regularly for blood estimations. The blood-thiocyanate level was kept at 4–8 mg. per 100 c.cm. After two weeks her headaches were

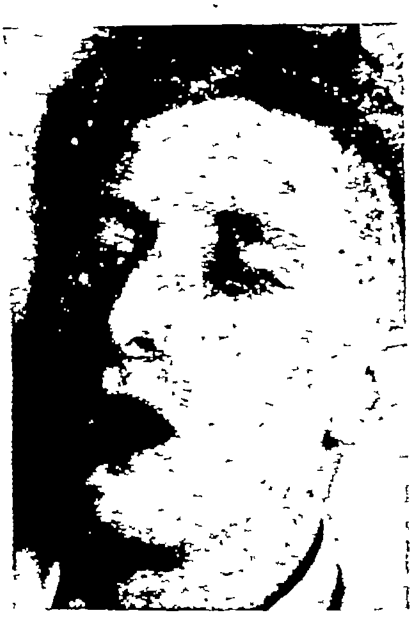

Fig. 3—Lesion on eyes, nares, and mouth.

Blood-culture was sterile.

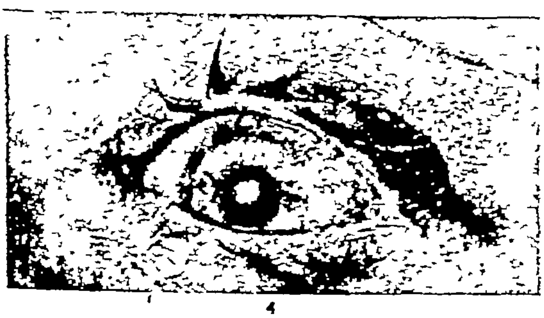
The temperature came down to normal on June 1 and remained normal (fig. 6). The eyes were now clear, but the mucosa of the mouth was still inflamed and purulent, and the patient salivated excessively. The urethritis was still severe but improving. The skin of the penis and part of the scrotum were excoriated.

The patient's general condition was now rapidly improving, and the lesions were gradually receding. By June 3 the skin lesions were only brown discoloured patches. There was no scarring. The lung signs had lasted only two days. The patient was now eating voraciously.

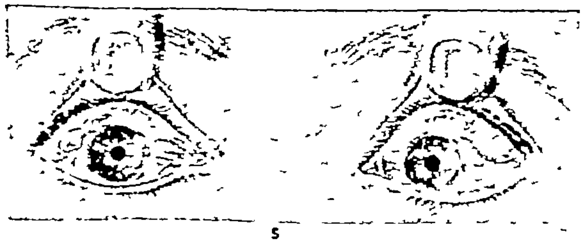
On the 13th the mouth was clear, and the urethral discharge had disappeared. The prepuce, however, was densely adherent to the glans penis and could not be retracted; circumcision was therefore performed. On the 21st the patient was allowed up, and two weeks later he was discharged well.

DISCUSSION

Very few cases of this syndrome occur in females. The age-incidence seems to be between 22 months and 19 years. Of 9 reported cases collected by Ageloff (1940) only 2 escaped total blindness, and these remained partially blind. The ocular lesions include corneal ulceration with scar formation; bilateral suppurative keratitis with perforation, leading to phthisis bulbi and total blindness: chemosis, subconjunctival hæmorrhage, iridocyclitis, and hazy corneas, with vision limited to partial perception of light; and pseudomembranous conjunctivitis, with corneal involvement and symblepharon.



4



5

Figs. 4 and 5—Eye lesion twelve days after admission.

The condition in the mouth varies from simple stomatitis and gingivitis to a severe pseudomembranous inflammatory process, with great swelling of the mucosa, tongue, lips, palate, and cheek, causing much pain in swallowing. Healing is usually complete.

The cutaneous lesions have been described as maculopapular, occasionally vesicular and bullous. These resolve as a rule with crusting and scaling, occasionally leaving brown and pigmented areas which finally disappear. The average time for resolution of the skin lesions appears to be 18–21 days.

The ætiology must be regarded as unknown. Chick and Witzberger (1938) described a case accompanied by Vincent's infection of the mouth and suggested Vincent's organisms as an ætiological agent, but this view has not been substantiated by other workers. Sutton and Sutton (1939) believe that the most likely explanation of the condition is allergic sensitisation. Biopsy in our cases and in others (Ageloff 1940, Edgar and Syverton 1938) have revealed only a non-specific inflammation of the skin. Erythema exudativum multiforme, as first described by Hebra (1866), is characterised by a maculopapular or vesicular eruption on the face, neck, and extensor surfaces of the hands, forearms, and legs. Hebra, however, emphasised the absence of constitutional symptoms and the presence of only mild, if any, oral or ocular involvement. Nevertheless Stevens-Johnson disease may be a severe or atypical form of this condition.

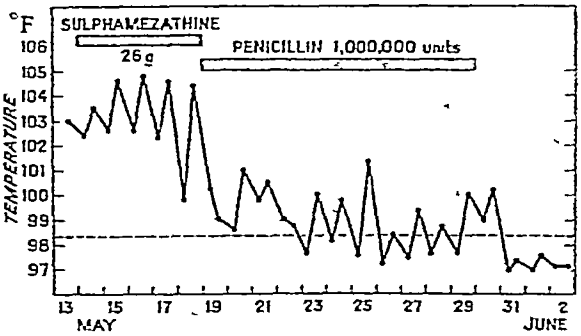


Fig. 6—Temperature chart.

The present case is very similar in many features to the disease seen in two men, aged 19, by Kove (1945). One of his cases was treated with sulphadiazine, with complete recovery. The second was desperately ill and had both sulphadiazine and penicillin. After three months' stay in hospital complete recovery resulted, except for mild chronic conjunctivitis and bilateral ocular synechiæ. In neither of his cases were the lungs affected. In our case there was undoubtedly a transitory pulmonary consolidation, confirmed radiologically, though the sputum did not become more profuse with the onset of the pneumonic lesion, and the flora did not change.

SUMMARY

A case of fever, associated with severe constitutional symptoms and eruptions affecting the skin and mucosa (stomatitis, conjunctivitis, and urethritis), is described.

I wish to thank Mr. E. V. Willmott, A.R.P.S., for the photographs.

headache is a predominating and troublesome symptom and does not respond to simpler forms of therapy. In many such cases, however, the effects of potassium thiocyanate were very striking and gave great relief, and therefore the drug should not be withheld if its administration is practicable.

This drug does not affect the course of the disease; nor does it permanently lower the blood-pressure, even in cases in which there is much symptomatic improvement. Potassium thiocyanate should be regarded purely as a palliative, so it has a limited though definite place in therapeutics.

STEVENS-JOHNSON SYNDROME

REPORT OF A CASE

MAURICE NELLEN
M.B. Cape Town, M.R.C.P., M.R.C.P.E.
JUNIOR LECTURER IN MEDICINE, BRITISH POSTGRADUATE MEDICAL SCHOOL, LONDON

IN 1922 Stevens and Johnson in the U.S.A. called attention to a syndrome characterised by fever, a bullous skin rash, stomatitis, and ophthalmia. According to Rosenberg and Rosenberg (1940) the first cases were described in France by Alibert and Bazin in 1822. Other examples have been reported under the names "erythema exudativum multiforme bullosum with conjunctivitis and stomatitis," "erythema exudativum multiforme pluriorificialis," or "Stevens-Johnson syndrome," but the condition is so rare that few clinicians are familiar with it.

The following case was seen at the British Postgraduate Medical School in 1945.

A man, aged 20, was admitted on May 13, 1945, with severe malaise, sore throat, and vomiting. Four days before admission he had developed a productive cough and felt generally unwell. A day later he had started vomiting after food and lost his appetite. Two days before admission his eyes had felt gritty, especially in the morning, and he had been unable to open them owing to pain and discharge. The day before admission he had had pain on micturition. There was no previous history of any important illness.

His temperature was 103° F, pulse-rate 100/min., respirations 30/min. There was bilateral conjunctivitis, numerous small vessels running inwards from either canthus towards, but not reaching, the limbus. There were also some vesicles on the conjunctiva. The discharge from the conjunctiva was mucopurulent. The nares were ulcerated, and the upper lip was covered with pustules. On the inside of both cheeks there were numerous discrete white patches, up to ¼ inch across, which could not be scraped off. There were also patches of white exudate on the tonsils. There was no urethral discharge. There were numerous rhonchi over both lungs. The liver was not enlarged and the spleen was not palpable.

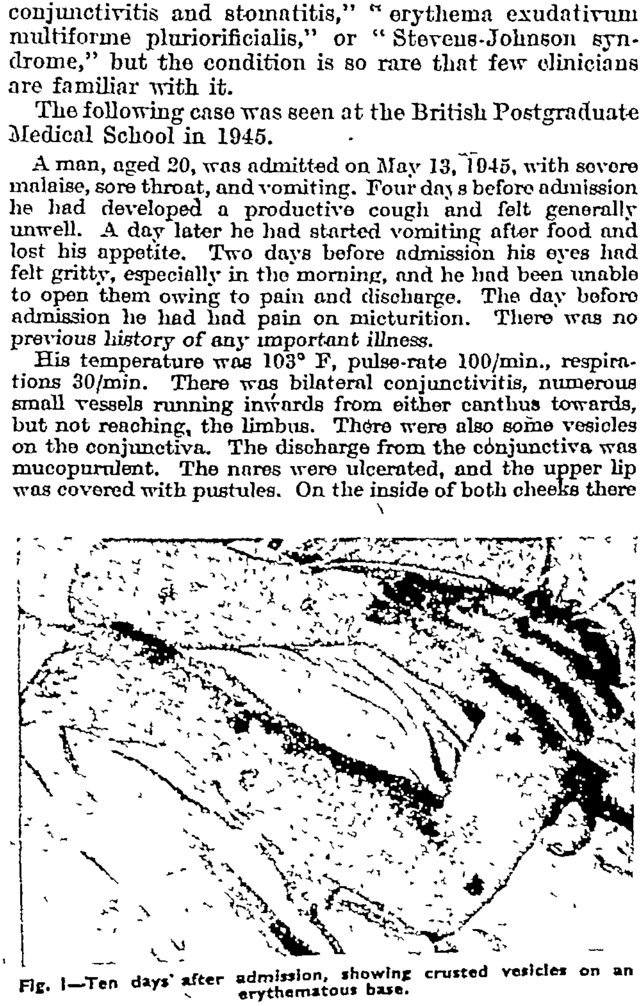

Fig. 1—Ten days' after admission, showing crusted vesicles on an erythematous base.

Report on throat swab next day: "No hæmolytic streptococci, no *C. diphtheriæ*, no Vincent's organisms." The sputum culture grew *H. influenzæ*, *Strep. pneumoniæ*, and neisseriæ. The blood-count showed red cells 4,500,000 per c.mm., Hb 94%, leucocytes 8000 per c.mm. (polymorphs 75%, lymphocytes 20%, monocytes 5%). Wassermann and Kahn reactions were negative.

Progress.—On May 15 a purulent urethral discharge developed. This grew no predominant organism on culture. Vesicles on an erythematous base were now appearing on the skin of both arms. The vesicles contained a pale fluid which was sterile on culture and free from cells. The vesicles were mostly on the dorsum of the arms (fig. 1).

On May 17 the same type of vesicle appeared on the thighs and legs, more on the extensor than on the flexor surfaces (fig. 2), and on the lower chest and abdomen. The vesicles varied in size and tended to crust early, the skin over them being dark.

The patient by now presented a florid picture; pus was pouring from the eyes and mouth (fig. 3) and from the urethra; the sputum was copious and purulent; the temperature ranged from 102° to 104° F, not responding to 'Sulphamezathine.' Pulse-rate 110/min., respirations 30/min.

On the 19th penicillin therapy was begun, 15,000 units being injected intramuscularly every three hours. The general condition improved, as judged by the temperature and the patient's subjective symptoms, but the lesions remained the same. The temperature now varied between 99° and 101° F.

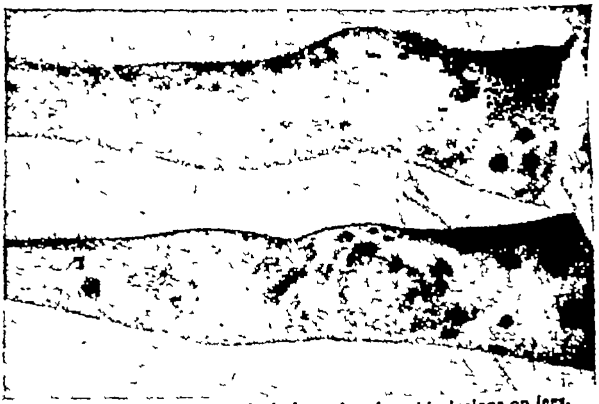

Fig. 2—Ten days after admission, showing skin lesions on legs.

The eyes (figs. 4 and 5) were seen by Dr. P. M. Moffatt, who reported on the 24th that the skin of the upper lids presented scabs of subsiding vesicles; in the conjunctivæ were elongated greyish swellings (fig. 5) which appeared to contain turbid fluid; and there were some granular swellings in the upper quadrants of the bulbar conjunctivæ, possibly the remains of vesicles which had subsided. Subconjunctival ecchymoses surrounded the limbus of each eye. The palpebral conjunctivæ showed nothing more than congestion. There was some mucopus in the lower fornices. The corneæ were clear and the fundi normal. The patient had a feeling of soreness and grittiness in the eyes and discharge. He resented exposure to bright light during examination. Irrigations with boric-acid lotion and eye-drops of 'Albucid' 10% every two hours were prescribed.

These swellings disappeared from the conjunctivæ by June 1, but there was still some congestion of the conjunctival blood-vessels, and traces of the ecchymoses could be seen. The watering and discharge were much less. The condition cleared by June 15, except for some slight injection of the conjunctival blood-vessels.

On May 28 the patient developed slight consolidation at the base of the right lung, with a pleuritic rub. There was a severe cough, with much watery and viscid sputum, which clung to the gums and teeth.

The throat swab at this time grew a heavy growth of *Staph. aureus.* A biopsy specimen of one of the vesicular lesions on the arm showed "slight vascular engorgement of the corium and a little œdema of the malpighian cells."

until complete resolution on the 19th day of illness. The papules had scaled off and the vesicles had dried by the 14th day of illness. Red or brown stains remained at the sites of the papulovesicular lesions, but there was neither pitting nor induration. The last areas to clear were the hands and feet.

DIFFERENTIAL DIAGNOSIS

In both patients the rash might have been mistaken for erythema multiforme, but the character and distribution of the lesions, the absence of burning and tingling, the formation of vesicles in the mouth, and the severity of the illness were against such a diagnosis.

The absence of the usual prodromata and backache, the distribution and character of the papules, their failure to mature, and the appearance of fresh spots over a period of some days excluded smallpox.

The bullæ in the mouth suggested pemphigus, but the development of the skin vesicles on existing papules and not on normal skin, the absence of raw areas on rupture of the skin vesicles, and the course of the illness were against it.

The possibility of a drug rash was considered, but in neither patient did the character of the exanthem or enanthem or the history support this diagnosis.

COMMENTS

The clinical picture presented by these cases appears to have been described in America by Stevens and Johnson (1922). I have been unable to find any reference to its occurrence in England, apart from a brief communication by Dowling (1940), who reports having seen, during the winter of 1939–40, six cases which resemble the two recorded here. He mentioned pemphigus, erythema multiforme, and smallpox in the differential diagnosis of his cases, but concluded that they were a reaction to a specific infection, probably streptococcal.

Though both my cases had stomatitis, conjunctivitis, and rash, apparently this triad may not always be present. In one of Dowling's patients mouth, penis, and scrotum were alone attacked, but in all six of his cases the genitalia were involved.

Kove (1945), who reviewed the American reports and described further cases, expresses the opinion that the enanthem rather than the exanthem is the most constant feature of the Stevens-Johnson syndrome. He records a case where the rash was limited to a superficial area of erythema with crusting in the urethral orifice and mentions that the rash may be macular, papular, or vesicular, and that it varies in severity in individual cases. In some of his own cases the vesicles on the hands became confluent and increased in size to several square centimetres, the desquamation of such vesicles not being complete until the 31st day. Stevens and Johnson (1922) state that new skin lesions may appear up to the 18th day of illness.

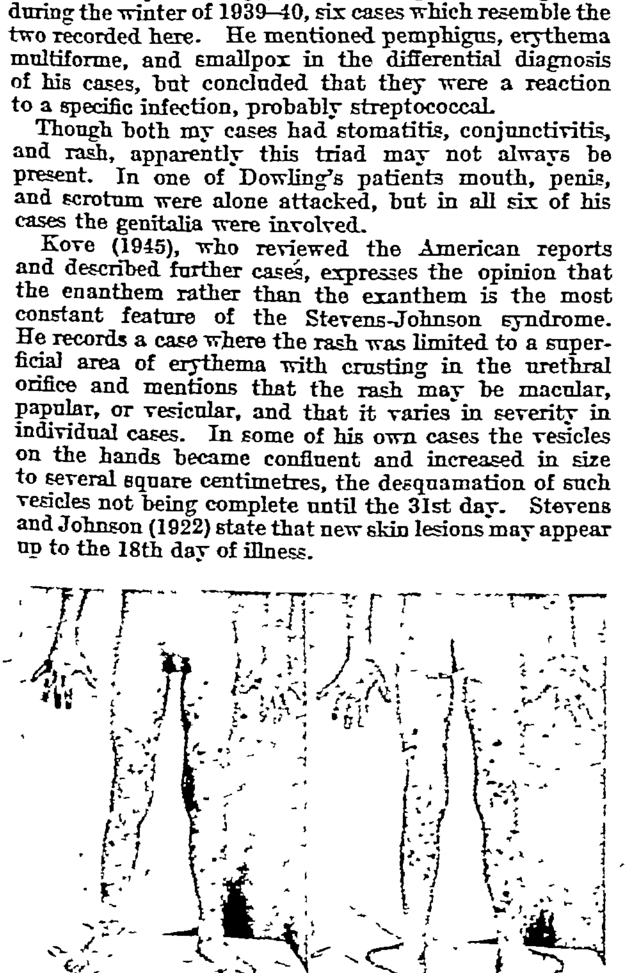

Fig. 2—Case 2, showing distribution of rash on limbs.

Stomatitis appears to be a constant feature of the syndrome and may be severe enough to make swallowing difficult and to necessitate intravenous infusions. According to Kove (1945) the sloughing of membranous exudation in the mouth may continue up to the 30th day.

The involvement of the eye may be serious. In two cases described by Stevens and Johnson (1922) there resulted blindness in one and impaired vision in the other.

The patients may be acutely ill. Temperature of 106° F, with profound prostration and toxæmia on the 2nd day of illness, has been recorded (Kove 1945). Fever may persist for some weeks (Stevens and Johnson 1922, Kove 1945) or may be of short duration, as in the two cases recorded here (4–6 days).

This syndrome may be preceded by or coincident with other conditions. In both my cases there was an antecedent lesion of the lips; circumoral herpes in one case, and an infected laceration in the other. One case recorded by Kove (1945) was preceded by mumps, the patient being in hospital five days before fever, stomatitis, and conjunctivitis developed. Cases associated with Vincent's angina (Chick and Witzberger 1938) and complicated by a bronchopneumonia or otitis media (Kove 1945) have been described.

Either a leucopenia or a mild leucocytosis may be present, but there are no characteristic laboratory findings (Kove 1945). A very comprehensive laboratory investigation was made in one case by Edgar and Syverton (cited by Kove 1945), who failed to recover a transmissible agent from vesicular fluid by animal inoculation.

I wish to thank Dr. E. T. Conybeare, of the Ministry of Health, for his interest in these cases and for drawing my attention to the published work; and Prof. A. W. Downie and Dr. E. R. Jones, Kent County pathologist, for the laboratory investigations.

URINARY EXCRETION OF PHOSPHATASES IN MAN

A. S. V. Burgen
M.B. Lond., M.R.C.P.

From the Department of Pharmacology, Middlesex Hospital Medical School

Various methods have been used to estimate urinary phosphatase. Demuth (1925), Dmochowski (1933), Kutscher and Wolbergs (1935a and b), and Kutscher and Wörner (1936) all estimated the phosphate liberated from various ester phosphates. The fact that there are in urine relatively large amounts of inorganic phosphate which cannot be removed without loss of phosphatase reduces the accuracy of this method. Rabaté and Courtois (1941) estimated the glycerol liberated from sodium glycerophosphate with periodic acid and iodine titration, but the method is insensitive, and glycerophosphate is a poor substrate for acid phosphatase. The method of King and Armstrong (1934) could not be used directly, because the Folin-Ciocolteu reagent for phenol reacts strongly with uric acid, and the precipitation of uric acid by silver lactate (Folin and Denis 1915) is tedious and time-consuming; Scott and Huggins (1942), however, removed the chromogenic substances by twelve hours' dialysis and then used the King-Armstrong method.

The method we finally adopted was to use monophenyl phosphate substrates and to estimate the liberated phenol by the very sensitive diazo method of Theis and Benedict (1924), which is unaffected by uric acid. The urinary phenols do not interfere with the estimation except in very concentrated urines, which should be diluted before

STEVENS-JOHNSON SYNDROME

REPORT OF TWO CASES

J. O. MURRAY
M.D. Edin., D.P.H.
MEDICAL OFFICER OF HEALTH, CITY OF ROCHESTER

EARLY in 1945 a patient was admitted to St. William's Infectious Diseases Hospital, Rochester, with an unusual eruption which was not typical of any common exanthem or any well-known skin disease. Just over a year later another patient with a similar skin condition was admitted to the same hospital. There was no connexion between these two patients, and on neither occasion were any further cases observed among contacts or persons residing near them.

CASE 1.—A boy, aged 16 years, a clerk, with a previous history of measles, whooping-cough, mumps, and chickenpox in early childhood, had been playing rugby football on Feb. 10, 1945, when he received a kick which split his lower lip and adjoining skin; no sutures were inserted. The injury caused him some local discomfort, but he felt well enough to continue work until the 23rd, when he became feverish, with headache, sore eyes and mouth, and diffuse pains in the limbs. He went to bed and later in the day noted spots on his thighs and arms. During the next two days similar spots appeared on the lower abdomen and shoulders. He was admitted to hospital on the 26th, up to which time he had not taken any drugs.

On admission: He was well nourished, mentally alert, and complained of discomfort in mouth and eyes only. No abnormalities were found in his cardiovascular, respiratory, nervous, lymphatic, or genito-urinary systems; temperature 97° F, pulse-rate 84, respirations 20 per min.

Mouth: There was a black scab at and adjoining the site of his lip injury. The pharynx was slightly inflamed. Lips were fissured and encrusted with blood and bled easily. There were irregular patches of greyish membrane on the buccal mucosa, tongue, and gums. Some patches were black from extravasated blood, and where the membrane was sloughing there were superficial red ulcerated areas on the tongue. The membrane was about 2 mm. thick. He could eat only with great discomfort but took fluids freely.

Eyes: The eyelids were slightly swollen, and the palpebral and bulbar conjunctivæ were injected; there was a slight purulent discharge from both palpebral fissures.

Skin: The rash was centrifugal in distribution and mainly symmetrical but did not favour extensor surfaces; it was profuse on hands, feet, legs, and forearms, and was well marked on thighs and buttocks. Except near the symphysis pubis, the trunk was free, as were the face and scalp. The skin lesions were painless and free from irritation.

The eruption consisted of macules and papules, most being about 0·5 cm. in diameter, though a few were over 1 cm. in diameter. They were oval or circular and superficial. The intervening skin was unaffected. The papules were slightly raised and surrounded by small irregular erythematous areolæ. There was no vesiculation or pustulation. The papules were matt red, some having a purplish or violet tinge.

Temperature, pulse-rate, and respiration were normal throughout his stay in hospital, and there were no toxic manifestations. Mouth discomfort was the worst feature. There was no diarrhœa or vomiting.

Treatment consisted of eye douches of boric-acid solution, frequent alkaline antiseptic mouth-washes, and swabbing: sulphapyridine was given for four days after admission.

Progress. The eye lesions had cleared by three days after admission (7th day of illness), and there was evidence of improvement in the stomatitis after four days' treatment, the mouth becoming free from membrane by the 16th day of illness, by which time epithelisation was well established, though there was some residual cheilosis.

The macules noted on admission chiefly on forearms and hands had become papular within a few days. There was no vesiculation at any time, though some papules eventually showed a whitish dry desquamative centre. By the end of a week (11th day of illness) all the papules were receding, becoming flat and hard before dropping off. They had disappeared completely by the 21st day of illness, the last to disappear being on the palms. Irregular circular pigmented areas, reddish-brown or faintly violet in tinge, remained to mark the sites of the lesions. On the palms this staining persisted for 8 weeks from the onset of illness.

CASE 2.—A cabin boy, aged 15 years, was admitted to hospital for observation as a smallpox suspect on March 11, 1946. He had had coryza, with some circumoral herpes, for several days but was not off work and did not feel ill.

On the 6th his mouth and tongue had become sore, and next day he had had headache, giddiness, shivering, and diffuse pains in the limbs (but no backache), and his eyes had begun to smart and water. He took to his bed, and on the 9th spots appeared, first noted round both ankles. Later in the day they were seen on the legs, but the rash did not appear on the arms until the evening.

He noted fresh spots on the legs, forearms, hands, and scrotum on the 10th. After this date no other spots appeared. His only previous illness was diphtheria in 1940. There was no evidence of successful vaccination.

On admission: A thin youth with delayed development of the secondary sex characteristics. Though below average intelligence, he was alert and coöperative during examination. There was no toxæmia. Temperature 98·4° F; pulse-rate 84; respirations 22 per min. No abnormalities were found apart from mouth, eye, and skin lesions.

Mouth: The lining mucosa of his lips and mouth were swollen. Lips and gums were bleeding slightly; black blood was encrusted on the fissured lips (fig. 1). On the gums, buccal mucosa, and tongue were large patches of greyish membrane 2–3 mm. thick; one vesicle containing clear fluid was noted on the palate. In some areas the membrane was sloughing, leaving raw superficial bleeding areas. The swelling of the mouth and tongue, and the discomfort of the patient, prevented a clear view of the fauces, which, so far as could be seen, were not involved. Breath was very offensive, the odour resembling that of diphtheria.

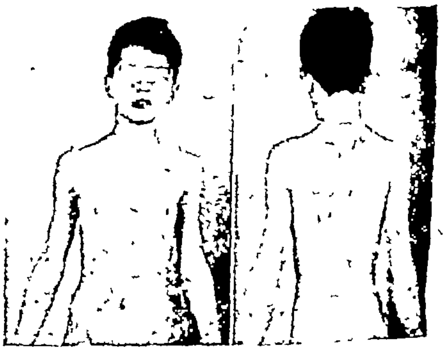

Fig. 1—Case 2, showing absence of rash from trunk.

Eyes: The eyelids were swollen and the conjunctivæ œdematous and injected. There was a profuse purulent discharge from both eyes. Culture of pus gave a growth of *Staph. pyogenes.* There was no corneal involvement.

Skin: A profuse papular and vesicular rash involved all areas except the face, scalp, and trunk, which were quite free (figs. 1 and 2). Two papules were present on the scrotum. The rash was most profuse on the hands. There was no preference for extensor surfaces.

In appearance the rash at first was similar to that in case 1 but later differed in that many, but not all, of the papules became vesicular, without, however, showing either loculation or umbilication. The vesicular fluid was faintly turbid. The papules *ruptured from one to three days* after their appearance.

The fluid from a vesicle was examined by Prof. A. W. Downie, of Liverpool, for variola-vaccinia antigen and proved negative. A differential blood-count on the 20th showed polymorphonuclear neutrophils 47%, eosinophils 2%, basophils 1%, monocytes 6%, lymphocytes 44%. No abnormal cells were seen.

Treatment. The eyes were frequently douched with boric-acid solution, and 'Collosol argentum' was instilled thrice daily. The mouth was treated with antiseptic mouth-washes and swabbing. Penicillin cream was applied to the mouth and skin lesions. No internal treatment was given.

Progress. On the 3rd day after admission (9th day of illness) the papules were beginning to shrink, vesicles had ruptured and some were beginning to dry, but at this stage the mouth showed little improvement. The eyes were free from swelling, injection, and discharge by the 11th day of illness. By this time there was a definite improvement in the stomatitis, and improvement continued uninterrupted until complete resolution on the 19th day of illness. The papules had scaled off and the vesicles had dried by the 14th day of illness. Red or brown stains remained at the sites of the papulovesicular lesions, but there was neither pitting nor induration. The last areas to clear were the hands and feet.

DIFFERENTIAL DIAGNOSIS

In both patients the rash might have been mistaken for erythema multiforme, but the character and distribution of the lesions, the absence of burning and tingling, the formation of vesicles in the mouth, and the severity of the illness were against such a diagnosis.

The absence of the usual prodromata and backache, the distribution and character of the papules, their failure to mature, and the appearance of fresh spots over a period of some days excluded smallpox.

The bullæ in the mouth suggested pemphigus, but the development of the skin vesicles on existing papules and not on normal skin, the absence of raw areas on rupture of the skin vesicles, and the course of the illness were against it.

The possibility of a drug rash was considered, but in neither patient did the character of the exanthem or enanthem or the history support this diagnosis.

COMMENTS

The clinical picture presented by these cases appears to have been described in America by Stevens and Johnson (1922). I have been unable to find any reference to its occurrence in England, apart from a brief communication by Dowling (1940), who reports having seen, during the winter of 1939–40, six cases which resemble the two recorded here. He mentioned pemphigus, erythema multiforme, and smallpox in the differential diagnosis of his cases, but concluded that they were a reaction to a specific infection, probably streptococcal.

Though both my cases had stomatitis, conjunctivitis, and rash, apparently this triad may not always be present. In one of Dowling's patients mouth, penis, and scrotum were alone attacked, but in all six of his cases the genitalia were involved.

Kove (1945), who reviewed the American reports and described further cases, expresses the opinion that the enanthem rather than the exanthem is the most constant feature of the Stevens-Johnson syndrome. He records a case where the rash was limited to a superficial area of erythema with crusting in the urethral orifice and mentions that the rash may be macular, papular, or vesicular, and that it varies in severity in individual cases. In some of his own cases the vesicles on the hands became confluent and increased in size to several square centimetres, the desquamation of such vesicles not being complete until the 31st day. Stevens and Johnson (1922) state that new skin lesions may appear up to the 18th day of illness.

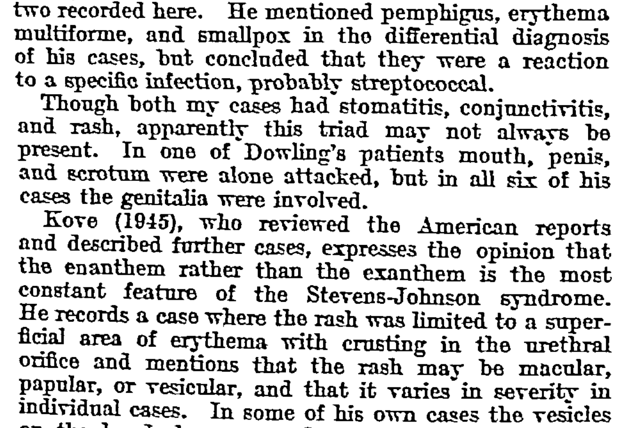

Fig. 2—Case 2, showing distribution of rash on limbs.

Stomatitis appears to be a constant feature of the syndrome and may be severe enough to make swallowing difficult and to necessitate intravenous infusions. According to Kove (1945) the sloughing of membranous exudation in the mouth may continue up to the 36th day.

The involvement of the eye may be serious. In two cases described by Stevens and Johnson (1922) there resulted blindness in one and impaired vision in the other.

The patients may be acutely ill. Temperature of 106° F, with profound prostration and toxæmia on the 2nd day of illness, has been recorded (Kove 1945). Fever may persist for some weeks (Stevens and Johnson 1922, Kove 1945) or may be of short duration, as in the two cases recorded here (4–6 days).

This syndrome may be preceded by or coincident with other conditions. In both my cases there was an antecedent lesion of the lips; circumoral herpes in one case, and an infected laceration in the other. One case recorded by Kove (1945) was preceded by mumps, the patient being in hospital five days before fever, stomatitis, and conjunctivitis developed. Cases associated with Vincent's angina (Chick and Witzberger 1938) and complicated by a bronchopneumonia or otitis media (Kove 1945) have been described.

Either a leucopenia or a mild leucocytosis may be present, but there are no characteristic laboratory findings (Kove 1945). A very comprehensive laboratory investigation was made in one case by Edgar and Syverton (cited by Kove 1945), who failed to recover a transmissible agent from vesicular fluid by animal inoculation.

I wish to thank Dr. E. T. Conybeare, of the Ministry of Health, for his interest in these cases and for drawing my attention to the published work; and Prof. A. W. Downie and Dr. E. R. Jones, Kent County pathologist, for the laboratory investigations.

URINARY EXCRETION OF PHOSPHATASES IN MAN

A. S. V. Burgen
M.B. Lond., M.R.C.P.

From the Department of Pharmacology, Middlesex Hospital Medical School

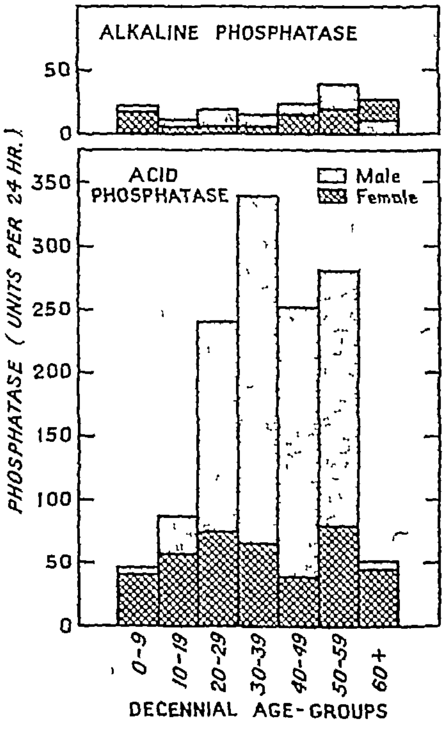
Various methods have been used to estimate urinary phosphatase. Demuth (1925), Dmochowski (1933), Kutscher and Wolbergs (1935a and b), and Kutscher and Wörner (1936) all estimated the phosphate liberated from various ester phosphates. The fact that there are in urine relatively large amounts of inorganic phosphate which cannot be removed without loss of phosphatase reduces the accuracy of this method. Rabaté and Courtois (1941) estimated the glycerol liberated from sodium glycerophosphate with periodic acid and iodine titration, but the method is insensitive, and glycerophosphate is a poor substrate for acid phosphatase. The method of King and Armstrong (1934) could not be used directly, because the Folin-Ciocolteu reagent for phenol reacts strongly with uric acid, and the precipitation of uric acid by silver lactate (Folin and Denis 1915) is tedious and time-consuming; Scott and Huggins (1942), however, removed the chromogenic substances by twelve hours' dialysis and then used the King-Armstrong method.

The method we finally adopted was to use monophenyl phosphate substrates and to estimate the liberated phenol by the very sensitive diazo method of Theis and Benedict (1924), which is unaffected by uric acid. The urinary phenols do not interfere with the estimation except in very concentrated urines, which should be diluted before estimation. Phenolic drugs, especially salicylates and sulphonamides, interfere with the reaction. In all cases 24-hour specimens of urine were used for the estimation.

METHODS

Preparation of Alkaline Substrate, pH 9·4.—Dissolve 10·3 g. of sodium barbitone and 1·09 g. of disodium phenyl phosphate in 1 litre of water.

Preparation of Acid Substrate, pH 4·9.—Dissolve 18·91 g. of citric acid in 180 c.cm. of normal NaOH, dilute to about 500 c.cm. with water, then add 100 c.cm. of *N*/10 HCl and 1·09 g. of disodium phenyl phosphate, and make up to 1 litre with water. Add a few drops of chloroform as a preservative and keep in the refrigerator.



Daily output of phosphatase in King-Armstrong units in decennial age-groups.

Phosphatase Determination.—(1) In two test-tubes put 10 c.cm. of substrate, and place the tubes in a water-bath at 37·5° C. After five minutes add 0·5 c.cm. of urine which has been diluted with an equal volume of water, and mix. After exactly thirty minutes add 2 c.cm. of protein precipitant (one part of 10% sodium tungstate, one part of $^2/_3 N$ H_2SO_4, and eight parts of distilled water), mix by inverting several times, and remove from the water-bath. If the solution becomes cloudy, allow it to flocculate for five minutes, then centrifuge, and remove 10 c.cm. of the supernatant fluid; otherwise transfer 10 c.cm. of the solution to a clean tube and add 1 c.cm. of 1% gum acacia, 1 c.cm. of 50% sodium acetate, and 1 c.cm. of phenol reagent (1·5 g. of *p*-nitroaniline dissolved in 40 c.cm. of conc. HCl and diluted to 500 c.cm.; take 25 c.cm., cool in iced water, add 0·75 c.cm. of 10% sodium nitrite, and mix; this reagent keeps for twenty-four hours). Mix and allow to stand for a minute, then add 2 c.cm. of 20% Na_2CO_3.

(2) An unincubated control is prepared by adding protein precipitant to a mixture of substrate and urine without preliminary incubation. Then proceed as above.

(3) A blank, prepared by using 10 c.cm. of water instead of the incubated substrate, gives a pale yellow colour.

(4) A standard is prepared by taking 0·5 c.cm. of standardised (10 mg. per 100 c.cm.) phenol (King and Armstrong 1934), which is equivalent to 25 units of phosphatase per 100 c.cm. of urine and gives an orange-red colour.

The colour was estimated in a Millikan photo-electric colorimeter, using a micro 3 green filter and setting to zero with the blank.

RESULTS

The results of the estimations in 50 males and 25 females out of an ordinary hospital population without genito-urinary disease are shown in the accompanying figure. The acid-phosphatase output in females is about the same for all ages, at a mean level of 50–60 King-Armstrong units per twenty-four hours. In males, however, a remarkable rise in the excretion begins in the second decade, reaches a maximum of 300–400 units in the fourth decade, and then falls away abruptly after the sixth decade, until it is almost equal to the female again. There was considerable intra-group variation, but the differences between males and females in age-groups 20–59 years were highly significant (P=0·01–0·001 by Fisher's "t" method). The alkaline-phosphatase excretion is scanty and highly irregular and shows no significant variation with age or sex.

The source of the urinary phosphatase has been the cause of speculation since Demuth (1925) surveyed organ and secretion phosphatases. Kutscher and Wolbergs (1935a) found a diurnal variation in the urine acid phosphatase which was maximal in the early morning and after lunch. These results were confirmed by Courtois and Biget (1943), who found a similar acid phosphatase in men after cystotomy and ablation of the prostate; their figures, however, were not significant quantitatively. Wolbergs (1936) found that the urine of adult women contained about a quarter of the phosphatase activity of the urine of adult men. Waldschmidt-Leitz and Nonnenburg (1935) suggested that the acid phosphatase was derived from the red blood cells, but King et al. (1945) showed that packed red cells contained 200–400 units of acid phosphatase per 100 c.cm., an amount sufficient to explain all the female output on the accepted rate of hæmolysis of the red blood cells but inadequate to explain most of the male output. Gutman and Gutman (1938, 1941) and Gutman (1942) have shown a rise in the acid-phosphatase content of the prostate from a few units per g. before puberty up to 250–1150 units per g. in the adult, and that prostatic fluid contains large amounts of the enzyme.

The great rise of acid phosphatase in the urine in the reproductive period of males points to most of the "excess" male over female output being derived from the prostate. Scott and Huggins (1942) found similar changes in the acid-phosphatase content of the urine and showed that the first part of the urine passed by males, which is known to have a greater prostatic admixture, contained more phosphatase than later samples. But 24-hour specimens which we collected from suprapubic cystotomy in 3 men gave values of 104, 140, and 223 units per day. These values, considering that the men's ages were 68, 66, and 55 years, are within the range for urethral urine at the same ages, suggesting that the urinary acid phosphatase is at least in part being excreted through the kidney and not directly into the urethra.

In disease of the prostate no significant difference in the output of acid phosphatase has been noted, either in benign hypertrophy or in carcinoma. Breedis et al. (1943) showed that there was a considerable decrease in the alkaline phosphatase in the kidney and an increased alkaline-phosphatase output in the urine of rats poisoned with uranium. Wilmer (1944) showed a similar decrease in the kidney alkaline phosphatase in human nephritis. In view of these findings it was thought that an increase in the alkaline-phosphatase output in the urine might be found in human nephritis. In a few cases of human acute, subacute, and chronic nephritis, however, no significant increase in the output of urinary alkaline phosphatase was found.

SUMMARY

The daily excretion of phosphatases in the urine of men and women has been examined.

The alkaline phosphatase is scanty and irregular and shows no variation with age or sex.

In females the average daily excretion of acid phosphatase is about 50 units at all ages.

In males the level of excretion is the same as in females in childhood, but from puberty onwards there is a sharp increase, reaching a maximum of 350 units in the fourth decade and falling off again in old age.

No alteration in phosphatase excretion has been found in disease of the prostate or in nephritis.

I wish to thank Prof. Samson Wright and Dr. D. Slome for much help and encouragement. The expenses of this research were partially defrayed by a grant from the Medical Research Council to Prof. Samson Wright.

Preliminary Communication

ACTIVITY OF PENICILLIN ESTERS

AMONG the various procedures for prolonging the time during which penicillin remains in the blood-stream at a therapeutic level, with an accompanying reduction in the rate of urinary excretion, the use of water-insoluble penicillin esters has been suggested. I have made a detailed study of the methyl and benzyl esters of "pure" penicillin, having an activity of 1500 I.U./mg. The details of this work will be published elsewhere in full[1]; meanwhile the general conclusions may be of interest to penicillin users.

I find that some species of animals, including mice, rats, and guineapigs, have in their sera an esterase that hydrolyses the methyl and benzyl esters of penicillin in 10 minutes. This enzyme, or complex of enzymes, is absent from the sera of rabbits and man. When the esters are injected into the rabbit or man no therapeutic effect is exerted. No penicillin can be detected circulating in the blood of rabbits or men during periods between 1 and 48 hours after injection. Furthermore, it appears that the ester, though it exerts no antibacterial effect, is destroyed in the body, for it cannot be found in the blood or urine of rabbits and men after injection. On the other hand, the enzymatic hydrolysis of these esters in mice, rats, and guineapigs, with the resulting liberation of penicillin, confers on them an antibacterial action of the same order as that of corresponding quantities of the free antibiotic.

These conclusions have consequences both in applied therapeutics and in laboratory technique. It is clear that the esters cannot have any value as compounds for prolonging the penicillin effect when injected into man, because, not being hydrolysed, they have no antibacterial effect at all. On the other hand, the existence of a penicillin esterase in the sera of mice, rats, and guineapigs makes these sera, particularly those of guineapigs, useful agents for investigating the effect of the esters in various species of animals. Incubation at 37°C with guineapig serum, for example, causes liberation from the methyl and benzyl esters of free penicillin, which can then be estimated in the usual manner. This method gives a convenient and quick method of detecting penicillin esters in different organs and body fluids, and should also prove useful in testing therapeutic agents.

Medical Societies

ASSOCIATION OF CLINICAL PATHOLOGISTS

THE association's annual meeting was held in London on Jan. 24 and 25, under the chairmanship of Dr. J. G. GREENFIELD.

The Interpretation of Blood-sugar Levels in Children

was discussed by Dr. J. L. EMERY, who showed cases of cœliac disease with clinical hypoglycæmia despite normal fasting blood-sugar levels. The pallor and sweating are relieved by glucose without a rise in the blood-sugar, and adrenaline also relieves the symptoms. Clinical manifestations should be recognised as real evidence of hypoglycæmia irrespective of the blood-sugar content, especially since symptoms may occur, even with a rising blood-sugar, following administration of insulin.

Dr. N. F. MACLAGAN described a *modification of the Lange colloidal gold curve* using buffered solutions. The advantages of buffered solutions are that they are more exactly reproduced and give more dependable results, because they are unaffected by traces of acid and alkali and because false positives are less common. The standard ten tubes are unnecessary since it is only the precipitation in the lower dilutions which indicates globulin increase.

Dr. B. E. TOMLINSON, speaking on the *chronic appendix*, said that there was no appreciable difference between the appendices in 100 surgical cases and those in 100 bodies following sudden death. In the surgical cases, however, localised inflammatory changes were seen in the internal muscle layer; these suggested a retrogressing lesion. Local areas of fibrosis and local collections of eosinophils were demonstrated in the muscle coats; but as far as the mucosa was concerned eosinophil counts were often higher in the controls than in the surgically removed appendices. He concluded with a plea for more exact pathological appraisal of the surgically removed appendix.

Dr. J. T. DUNCAN described the widespread lesions which may be found in *torula meningitis*. Infection, he suggested, usually takes place via the tonsil or by trauma of the skin, and the organism, *Cryptococcus neoformans*, has a predilection for the central nervous system and the lungs. It is hard to recognise this organism unless it is properly stained, preferably by muci-carmine. There are probably more cases of torula meningitis than is appreciated, for with a careful look-out they are identified fairly often.

Dr. V. D. ALLISON and Miss B. HOBBS discussed the *epidemiology of pemphigus neonatorum* from observation of 200 cases seen in one large and two small epidemics, using serological typing of *Staphylococcus pyogenes*. This showed that the sources of infection are the upper respiratory tract and skin of carriers. Carriers are commoner among nurses than the general public; and one series of cases originated from a carrier whose task it was to fold clean napkins in a laundry. It is important not to incriminate an attendant until it has been proved that the serological type found in her agrees with that causing the epidemic. It may be worth applying penicillin to the anterior nares of chronic tonsil carriers.

Dr. J. G. GREENFIELD, reviewing the *causes of cerebral abscess*, emphasised the importance, in the differentiation from meningitis, of estimating the sugar in the cerebrospinal fluid; this is early reduced with meningitis, while with abscess it usually remains normal until meningitis supervenes. Usually the cerebrospinal fluid is clear; the cell-count in his cases varied from 4 to 800 per c.mm., with lymphocytes predominating: and protein varied from 10 to 200 mg. per 100 ml. The organisms were very variable: of 45 cases, 15 were due to staphylococcus, 10 to anaerobic streptococcus, 10 to fusiform bacillus, 6 to *pneumococcus*, and 6 to *proteus*. The *prognosis* is best with pneumococcal and streptococcal infections.

Dr. C. E. DUKES, speaking on the *hereditary factor in polyposis of the intestine*, described families in which the disease was transmitted as a dominant character; the gene can be carried by male or female.

Dr. S. C. DYKE showed that in the *treatment of refractory anæmia with folic acid* there may be a double rise in reticulocytes. In pernicious anæmia and in refractory anæmias expected reticulocyte and red-blood cell levels are always reached. In 2 cases of pernicious anæmia with previous histamine-fast achlorhydria the acid returned in the gastric secretion after treatment with folic acid.

In a discussion on the *laboratory applications of the Rhesus factor* a general plea was made for the adoption of Fisher's nomenclature. It was considered that every prospective mother should be Rh-grouped, and that difficult cases should be referred to the laboratories at the Lister Institute.

Reviews of Books

A third edition has appeared of CLINICAL PRACTICE IN INFECTIOUS DISEASES (Edinburgh: E. & S. Livingstone, pp. 679, 22*s.* 6*d.*) by Dr. E. H. R. Harries and Dr. Maurice Mitman. After publication of the second edition in 1943, a fire at the printers destroyed the blocks, and made reprinting impossible. The book has therefore been completely revised, and contains a new chapter on the pneumonias, and short sections on the common cold, febrile herpes, epidemic nausea and vomiting, epidemic myalgia, and infective polyneuritis. The account of penicillin has been expanded, and a note added on streptomycin. Social conditions are discussed in relation to epidemiology, and more space has been given to "influenzal" meningitis, food-poisoning, homologous serum jaundice, typhus, virus diseases of the nervous system (which includes a critical review of the Kenny method of treating poliomyelitis), mass chemoprophylaxis, and many other subjects of recent and growing interest. This valuable work is thus larger by some 100 pages than in its last edition.

Dr. Wilfrid Sheldon's DISEASES OF INFANCY AND CHILDHOOD (5th ed., London: J. & A. Churchill, pp. 775, 30*s.*) bids fair to become as popular as Still's. The advent of penicillin is the outstanding new development since the last edition, and its use is well described in a brief appendix. The sections on tuberculosis, cœliac disease, and poliomyelitis have been revised, and growing interest in the newborn period is reflected in the text.

ACIDOSIS (London: W. Heinemann, pp. 225, 18*s.*) is written by Dr. Esben Kirk, chief physician to the medical service of Holstebro District Hospital, Denmark, and was first published in 1942 to convince his colleagues of the importance of treating acidosis with isotonic sodium bicarbonate solution. His specialised approach to the problem detracts from the value of his otherwise interesting survey of a perplexing problem; and few British clinicians will agree with his emphasis on isotonic sodium bicarbonate in the treatment of diabetic coma.

By recording belief as fact and omitting pros and cons, Prof. Rolland J. Main, PH.D., of the Medical College of Virginia, has usefully summarised the salient facts of human physiology. His SYNOPSIS OF PHYSIOLOGY (London: H. Kimpton, pp. 341, 18*s.*) is intended to serve as a quick reference book for students already acquainted with their subject. It gives plenty of numerical data, supplemented with useful tables and few but graphic diagrams. While unsuitable for either the advanced student or the beginner, it is satisfactory for its own purpose.

Dr. F. M. R. Walshe, F.R.S., writes in the preface to the 5th edition of his DISEASES OF THE NERVOUS SYSTEM (Edinburgh: E. & S. Livingstone, pp. 351, 16*s.*) that he has made such minor additions as the advance of knowledge, the flux of opinion, and the suggestions of correspondents make expedient. The student will again find the principles of neurological diagnosis and the common diseases of the nervous system well described; but the psychoneuroses are still given only 23 pages. It might be better to omit this section from a textbook in which it is hardly at home.

Nineteen new coloured photographs appear in the edition of Dr. Henry Semon's unique ATLAS OF THE Cu SKIN DISEASES (Bristol: J. Wright, pp. 343, 50*s.*), unfortunately some of them are below the original standard, the colour-values being erratic, or blurred. T text is terse and highly informative. It is noteworthy that Dr. Semon roundly condemns the local use of sulphonamides in skin diseases.

Prof. Maurice Loeper is professor of clinical medicine to the Faculté de Médecine of Paris. His collection of essays (HÉPATITES RARES, Paris: Masson, pp. 214, fr. 290) is not confined to hepatitis but includes chapters on oxaluria and liver disease, anæmia in cirrhosis, and cystic disease of the liver. The theories presented often seem strange, and many statements are unsupported by data. The bibliography refers mainly to Continental work.

Dr. F. M. Pottenger, medical director of his own sanatorium in California, sets out his views on the reflex action of the spinal and automatic systems in visceral disease. The 6th edition of his SYMPTOMS OF VISCERAL DISEASE (London: H. Kimpton, pp. 442, 25*s.*) is essentially the same as its forerunners. He urges the relationship of many apparently unconnected symptoms with the morbid process, sometimes using readily acceptable evidence, at others evidence which lacks scientific support. The work can only be recommended to those who know enough to read it critically.

In AMPUTATION PROSTHESIS (London: J. B. Lippincott, pp. 305, 50*s.*) Dr. Atha Thomas, associate professor of surgery in the University of Colorado, and Mr. Chester C. Haddan, president of the Association of Limb Manufacturers of America, have collaborated to discuss the problems faced by surgeon and limb-maker in fitting prostheses. They cover well such topics as the moulding of the stump by bandaging, re-education of the stump muscles, functional values of stumps of various lengths, and the training of the patient in the use of his limb, and they lay emphasis on the importance of fit and alignment. A good section deals with prostheses in children.

Mr. H. E. Cox, D.SC., is an experienced public analyst, and the techniques detailed in his CHEMICAL ANALYSIS OF FOODS (3rd ed., London: J. & A. Churchill, pp. 317, 24*s.*) are probably those commonly used in his laboratory. Though they have stood the test of time, many of them have been superseded in the eight years since the last edition, and might well have been omitted in this one. Thus the Kjeldahl method described is now out of date, and there is no mention of the selenide catalyst which has accelerated the tempo of all total nitrogen assays. Fuller accounts of some of the more modern methods would have been welcome. The scope of the book is wide, and there is an appendix on the preservative regulations and prohibited colouring matters.

Mr. W. H. Maxwell's compendious, indeed discursive, guide to the engineering side of water-supply (CURRENT WATERWORKS PRACTICE, London: B. T. Batsford, pp. 254, 18*s.*) will be useful on the M.O.H.'s reference shelf, and rural doctors will find it interesting in the light it throws on the problem of getting pure water into every home, however remote. The fact that gas prefers to run uphill and electricity doesn't mind is poor compensation for the fact that water refuses to do so; and the community is only just beginning to realise that gravity cannot be made an excuse for penalising the rural population. Mr. Maxwell might usefully turn his attention next to this side of the problem. His photographs of big dams and reservoirs are beautiful.

There are twenty contributors to PREOPERATIVE AND POSTOPERATIVE TREATMENT (2nd ed., London: W. B. Saunders, pp. 584, 35*s.*), under the editorship of Lieut.-Colonel Robert L. Mason, of the Cushing General Hospital, Framlingham, Massachusetts, and Dr. Harold A. Zintel, of the University of Pennsylvania school of medicine. In the first part, which covers such general problems as the management of the surgical patient with heart disease, the strong influence of physiology on American surgery is well seen. Of particular interest are the chapters on water balance and on postoperative venous thrombosis; in the latter, ligature of large veins is freely recommended. Though the second part, arranged under regional headings, is insufficiently concise and has important omissions—for example, the eye, and elective surgery of the chest and head are not mentioned—the book as a whole is interesting and instructive.

IN PERNICIOUS ANAEMIA—1cc. EXAMEN

Made more efficient by proteolysis . . .

Preliminary enzyme digestion of the liver—a proteolytic process—is an important advance in the manufacture of 'Examen'. This process breaks down the conjugations of the anti-anaemic factor and renders extraction more complete. The anti-anaemic factor is thus made totally available in therapeutically effective form. Likelihood of sensitization to liver is also considerably reduced.

The 1 cc. 'Examen' ampoule contains the standard dose for both initial and maintenance treatment of uncomplicated pernicious anaemia, this amount giving optimum blood cell regeneration over a period of 14 days. Every batch of 'Examen' is subjected to clinical trials before issue; and intramuscular injection of 'Examen' causes no pain or discomfort to the patient.

INJECTABLE **EXAMEN** LIVER EXTRACT

1 cc. ampoules: boxes of 3 and 6. 5 cc. vials: boxes of 1 and 5.

Vitamin Therapy—its uses and limitations

SUB-OPTIMAL NUTRITION

is known to be responsible for a variety of minor disorders which occur in the earlier stages of nutritive failure—for example, easy fatiguability, both mental and physical, functional digestive disorders with anorexia and gastro-intestinal atony, anæmia, emotional instability, neuritic pains and lowered metabolic rate. It is now generally agreed that such combinations of symptoms are seldom attributable to lack of a single factor and that the whole vitamin B complex is needed for treatment.

Oxford and Cambridge BOAT RACE (March 29)

We have space for a few doctors and friends at our Hammersmith Wharf. Please make early application for tickets.

BEFORTISS
B-complex capsules

Each capsule contains

Aneurin hydrochloride	1.0 mg.
Riboflavin	1.0 mg
Nicotinamide	15.0 mg
Pyridoxin	0.5 mg

THE LANCET

LONDON: SATURDAY, MARCH 15, 1947

First Things First

If we return again and again to the problems of nursing, it is because the coming effort to improve medical services in this country will be wholly frustrated unless there are enough nurses properly trained for their work. Since State registration was introduced in 1919 the General Nursing Council has been the body that decides what training is proper, and its curriculum has been one of the principal factors regulating recruitment to the profession. At a time, therefore, when this recruitment is patently insufficient, the council may fairly be asked to justify its requirements and to show that these are related to the requirements of the nation.

The question is all the more necessary because the syllabuses confronting the student nurse have just been redrafted, and apparently there is to be an increase rather than a decrease in the number of subjects covered. The draft has not been published, but at the council's meeting on Feb. 28 it moved a medical member, Dr. Russell Brain, to strenuous protest. It embodies, he said, the very faults that medical educators are trying to eliminate from the medical course, and many of the sort of facts that 90% of doctors forget as soon as they are qualified and never need again. Commenting on the proposed content of the 40 lectures leading up to the preliminary examination, he asked what for example is the use of the nurse knowing "the names and position of the bones of the cranium and face, the bony structure of the orbit, nose, mouth, and base of the skull, and the principal characteristics of the bones of the cranium, maxilla, and mandible," or the "special characteristics of vertebræ from the cervical, dorsal, and lumbar regions"—peculiarities of practical interest only to an orthopædic surgeon. All that can be said in favour of including the thymus, he thought, is that the little known about it could burden nobody's memory: but why should the nurse have to learn the effect of hyper- and hypo-parathyroidism? The "position, structure, and functions of the mid-brain, pons, and cerebellum" cannot usefully be considered without much more study than she has time for, and the same is true of "a brief outline of the limb plexuses." The title of the course is "elementary anatomy and physiology," but there is in fact no elementary way of dealing with such topics. Dr. Brain invited the council to refer the syllabus back to its education and examination committee, but he found no seconder for his motion. So the draft syllabus was passed, subject to the approval of the Ministry of Health.

A glance at papers set this year for the preliminary and final State examinations shows how cogent were Dr. Brain's objections to putting further detail into the syllabus:

> "Describe the shoulder girdle. What are the chief muscles attached to it?"
>
> "What do you understand by the term sewage effluent? What means are taken for its purification?"
>
> "Describe a case of acute rheumatic fever and give an account of the nursing and medical treatment of this condition. Enumerate the complications which might arise."

Why should the nurse be examined on the medical as well as the nursing treatment of a case? And what is gained? Having set a specialised question, the examiner finds himself obliged to mark it on a low standard, whereas a question of general importance can be marked on a high one. The nursing syllabus, even in its present form, contains too many items that are not of general importance. Admittedly, any or all of them might appropriately be mentioned in teaching a group of intelligent girls, but that is quite different from setting them down in black and white as subjects that may figure in the examination and must therefore be tackled by every conscientious student and every conscientious teacher, at Grimsby and Gillingham as well as at Guy's. Ability to divine *what is relatively unimportant, and pay no attention* to it, is not a gift with which young students are generally endowed.

The medical profession appreciates and admires the work of those who, both here and in America, have overcome great difficulties in their constant endeavour to raise the quality of nursing and the status of the nurse. As W. M. Firor,[1] the American surgeon, puts it, "the road travelled by the nursing profession has been a long and ever broadening one. The leaders have tried to keep nursing education abreast of the rapidly advancing front in medical knowledge." But this laudable effort, as he points out, has had "at least two undesirable consequences that make it imperative for the leaders in nursing education to pause and take their bearings. These . . . are: first, the failure of this program to attract and to hold an adequate number of young women to meet the needs of the country; and second, the nurse of today is not being trained primarily to care for the patient." Has not the time in fact come to reconsider the nursing curriculum in the light of its essential purpose? Education, alike for medicine and for nursing, should, we suggest, be directed always towards the good of the sick—not towards advancing the status of nurse or doctor. The General Nursing Council no doubt has the ultimate welfare of the sick very much in mind; yet, here as in America, there is reason to believe that "the nurse of today is not being trained primarily to care for the patient." Moreover the council, holding a position where its power exceeds its responsibility, seems sometimes to forget that, if patients are to be nursed at all, there must be not only good nurses but enough nurses. The present syllabus and examinations are too much for many girls who become student nurses, and so long as training is uniformly based on them a substantial proportion of useful entrants will be lost through discouragement and dismay. Certainly at this stage any increase of bookwork must make a bad situation worse. What is needed, on the contrary, is a shift of emphasis towards bedside nursing. We have to make arrangements that will attract well-educated women into a profession demanding all their powers, but will nevertheless permit any sensible girl to attain the title of nurse if she shows aptitude for the care of the sick.

---

[1] *Surg. Gynec. Obstet.* January, 1947, p. 122.

Cardiac Catheterisation and Beyond

THE technique of intracardiac catheterisation,[1] based *mainly on the pioneer work at the Bellevue* Hospital, New York, and on subsequent research in Atlanta and at the British Postgraduate Medical School, *continues to develop, and its use has now* spread to many hospitals in the United States as well as to Sweden, France, and Switzerland. In practised hands the method is free from risk and no more difficult than ureteric catheterisation; its applications are only beginning to be explored.

COURNAND and his colleagues [2] in New York have used the cardiac catheter for optically recording intracardiac pressure pulses on the right side of the heart. To the end of a catheter of sufficiently wide bore they attach a small membrane manometer recording optically on moving photographic paper. By means of a double-lumen catheter simultaneous records may be made from two parts of the cardiovascular system, such as the right auricle and ventricle, or the right auricle and peripheral veins. The maximum pressure reached in the right ventricle is, of course, the same as the systolic pressure in the pulmonary artery, and in normal people this has been found to average 25 *mm. Hg. In patients with emphysema without* heart-failure the pulmonary systolic pressures ranged from normal to 57·5 mm. Hg, and there was apparently no correlation between pulmonary hypertension and the severity of the emphysema. One case of mitral valve disease had a pulmonary systolic pressure of 43 mm. Hg though *there was no rise in the right* auricular pressure. When heart-failure develops, a whole series of changes take place in the intra-auricular and *intraventricular pressure curves. In a patient* with emphysema and heart-failure the pulmonary systolic pressure was raised to 68 mm. Hg, and in mitral stenosis with severe failure it was much higher—in one case it reached 103 mm Hg, falling to 57 mm. Hg as the patient recovered from the failure. In other forms of heart-failure (hypertensive and arteriosclerotic) the pulmonary systolic pressure rises to 50–80 mm. Hg. Ordinary arterial hypertension without failure, however, does not affect the pressures on the right side of the heart, the pressure in the pulmonary artery remaining normal. By studying the pulse pressure and the amplitude of the auricular and ventricular pressure waves conclusions can be drawn regarding the changes in output per beat during the respiratory cycle [3] Inspiration assists the filling of the chambers of the right heart, *so stroke* output is increased; while during expiration the output of the right auricle and ventricle falls. In the early part *of inspiration the increased output* of the right ventricle is accommodated in the lungs, but a little later the left ventricle gets the increased flow and the systemic arterial pressure rises. This technique opens up new possibilities for the detailed analysis of human cardiodynamics in health and disease.

Proceeding along simpler lines of measurement of filling pressure and output per minute, HOWARTH, MCMICHAEL, and SHARPEY-SCHAFER [4] at Hammersmith have continued *their* studies on heart-failure. They found that in "low output heart-failure" venesection lowers the venous pressure and raises the *output of the heart.* By *comparison in similar* grou of cases, they showed that lowering venous pressu by mechanical means and by digitalis have identic *effects on cardiac output. Venesection, howeve* lowers the blood-pressure, while digitalis may leave unchanged or even raised; so the heart is actuall doing more work *after digitalis than after venesectio* Whether this can be interpreted as a stimulating actio of digitalis on the heart is uncertain, but these studie seem to have established the importance of a primar reduction in venous pressure by *means of digitalis* i the treatment of the failing heart. WARREN an others [5] have drawn attention to the possibility errors in the estimation of cardiac output arisin from incomplete mixing of blood in the right auricl Duplicate samples taken in this situation were foun to differ from one another in oxygen content by mor than 0·4 vols. per cent. in a fifth of the cases studie Similar studies by COURNAND [6] showed, howeve that the differences between duplicate samples fro the right heart were very seldom more than 0·4 vol per cent MCMICHAEL [7] thinks that anomalous sample are obtained only about once in 20 cases. *Any* erro arising from incomplete mixing is readily detectabl by comparing right ventricular with right auricula samples and by duplicate sampling at *critical point* in all experimental observations; if this is done the results obtained should be highly accurate, but *isolated observations may be open to suspicion.*

The catheter's potentialities as an instrument of investigation do not end at the heart. A cathete *with an angle bend near the tip* can be passed through the auricle into the inferior vena cava, and unde fluoroscopic screen control it may be manipulated into the hepatic or renal veins. BRADLEY and his colleagues [8] have made quantitative studies of the hepatic blood-flow in man by an ingenious method Bromsulphthalein, a substance which is removed from the blood-stream by the liver, is infused into a vein at a rate equal to the rate of excretion, so that the blood-level remains constant. The concentration of bromsulphthalein in the blood entering the liver is taken to be the same as that in the peripheral blood, and by sampling the hepatic-vein blood the amount extracted from each 100 ml. can be *estimated.* A sampl calculation may make this clear.

Rate of removal (or infusion) of bromsulphthalein = *4 80 mg./min.; peripheral serum concentration* = 1·08 mg./ 100 ml.; hepatic vein serum level = 0·57 mg./100 ml; hæmatocrit = 43%.

$$\text{Estimated hepatic blood-flow} = \frac{4{\cdot}80 \times 100}{1{\cdot}08 - 0\ 57} \times \frac{100}{100-43}$$
$$= 1651 \text{ ml./min.}$$

A considerable range of values can be obtained in one subject—e g., from 945 to 1618 ml /min.—according to the position of the catheter in the liver It is possible that the rate of flow does vary in different parts of the liver, and it is a slight drawback to the method that *mixed* hepatic-vein blood cannot be obtained. BRADLEY and his colleagues, and WARREN

and others[9] have passed the catheter into the right renal vein. They studied the clearance of sodium *p*-aminohippurate by the kidney and found that, on the average, 85–88% is removed by the kidney, thus proving the value of clearance of this substance as an index of renal blood-flow. The further work with catheterisation of the renal vein now being done in America may throw light on some of the obscurities of renal physiology and pathology.

Epidemiology of Lobar Pneumonia

LOBAR pneumonia is an infectious disease caused most commonly by pneumococcus types I, II, V, and VII. Its greatest prevalence is among males of 15–65 and, though sulphonamides or penicillin can reduce the case-mortality by more than half, the disease is a major cause of illness and death in a very important section of the community. Yet little is known of its mode of spread, and few direct attempts have been made to control its incidence.

War-time outbreaks of pneumonia, among young men brought together for training, can be studied in more detail than is possible in civilian practice. **HODGES** and **MCLEOD**,[10] for example, describe experience in an army technical school in the Mid-west of the United States, where during three successive winters there were over 1600 cases of primary pneumococcal pneumonia, with a weekly attack-rate sometimes above 150 per 1000 men. The area has a hot dry summer and a bitterly cold winter, with long spells of cold damp weather in spring and autumn. The barracks and classrooms were of rude design with rough concrete floors that favoured dust, while the heating was uneven and ventilation in winter very poor. The men stayed 16–24 weeks in the camp, spending six hours a day in the classrooms, and apart from a continual influx and outflow the community of 8000–17,000 remained pretty well isolated. In short, the conditions were well suited to the epidemic spread of respiratory infections, especially in the first winter when most of the intake were new recruits. The first case of pneumonia was admitted in September, 1942, and in the following January there was a rapid increase in admissions, which remained at a high level until May when there was a sudden drop. Next winter the curve began to rise in November, reaching a peak in December, but the incidence was lower in the spring months, probably because sulphadiazine was used as a prophylactic. A big reduction in the third winter is attributed to inoculation with polysaccharides of the prevalent pneumococcal types. Other training-camps in the area did not have similar outbreaks and it seemed likely that acute respiratory disease among unseasoned troops in the first winter predisposed to dissemination of the epidemic pneumococci—whose order of frequency was type II (35% of all cases), I, V, VII, XII, and IV. Pneumococci of the epidemic types were found in the dust of both classrooms and barracks, in the same proportions as in the throats of carriers The investigators found no evidence that transfer from another climate, chill, or fatigue significantly predisposed to pneumonia.

During the third season an attempt was made to ascertain the relationship, if any, between carrier-rates and the incidence of pneumonia. The total pneumococcal carrier-rate, rising from 40% in the summer to 60–70% in the winter, bore no close relation to the incidence of pneumococcal pneumonia or other respiratory infections. There was a good correlation between the carrier-rate of specific epidemic types (e g., IV and XII, which were predominant in the third winter) and illness due to these types: yet carrier-rates of 10–20% of these two types were found in the early winter months, before there was much pneumonia. This suggests that some other factor had to come into play before clinical infection could take place, and **HODGES** and **MCLEOD** believe that this factor is an antecedent non-bacterial respiratory infection. The winter prevalence of pneumococcal pneumonia showed a close time-relation to upper-respiratory infections including influenza, with a relative incidence of 1 : 10: but in the first winter, when presumably there were few carriers of the epidemic pneumococcus types, an outbreak of acute respiratory disease was unaccompanied by pneumonia. When the carrier-rate became high outbreaks of influenza in 1943 and 1945 were associated with peaks of pneumococcal pneumonia. It is of course a traditional observation that pneumonia is often preceded by a common cold.

Against lobar pneumonia in civil life this study points to three lines of attack. The first is to reduce (where we can) the incidence of non-bacterial respiratory infections. The second is to reduce the carrier-rate of epidemic pneumococcus types in places where pneumonia is occurring with unusual frequency; for this purpose chemoprophylaxis might be effective, but in view of the viability of pneumococci in dust it should be combined with dust control. The third is to raise specifically the resistance of the susceptible community by inoculation with the capsular polysaccharides of the prevalent pneumococcus types. **MCLEOD** and his colleagues,[11] with a single injection containing 0·03–0·06 mg. of each of the polysaccharides of types I, II, V, and VII, practically eliminated pneumonia due to these four types in the treated group, while incidence in the control group was reduced probably because of an overall reduction in carrier-rates of these epidemic types: the incidence of pneumonia due to types XII and IV, against which no protection was attempted, remained unaffected. For groups of people exposed to abnormal risk of infection—such as foundry-workers, miners, and recruits in training-camps—this simple safeguard may well commend itself.

The National Situation

THE economic situation debated by Parliament this week must colour our lives for years to come. The means chosen to retrieve that situation will affect the whole social framework, of which medicine is a part. On another page a correspondent challenges the dictum "export or starve" and urges that instead of dislocating our economy by an increasingly difficult policy of forced exports we should set about producing far more food, ensuring rapid expansion of agriculture by paying higher prices to the farmer. The arguments advanced, and their sociological implications, deserve close attention.

Cardiac Catheterisation and Beyond

The technique of intracardiac catheterisation,[1] based mainly on the pioneer work at the Bellevue Hospital, New York, and on subsequent research in Atlanta and at the British Postgraduate Medical School, continues to develop, and its use has now spread to many hospitals in the United States as well as to Sweden, France, and Switzerland. In practised hands the method is free from risk and no more difficult than ureteric catheterisation; its applications are only beginning to be explored.

Cournand and his colleagues[2] in New York have used the cardiac catheter for optically recording intracardiac pressure pulses on the right side of the heart. To the end of a catheter of sufficiently wide bore they attach a small membrane manometer recording optically on moving photographic paper. By means of a double-lumen catheter simultaneous records may be made from two parts of the cardiovascular system, such as the right auricle and ventricle, or the right auricle and peripheral veins. The maximum pressure reached in the right ventricle is, of course, the same as the systolic pressure in the pulmonary artery, and in normal people this has been found to average 25 mm. Hg In patients with emphysema without heart-failure the pulmonary systolic pressures ranged from normal to 57·5 mm. Hg, and there was apparently no correlation between pulmonary hypertension and the severity of the emphysema. One case of mitral valve disease had a pulmonary systolic pressure of 43 mm. Hg though there was no rise in the right auricular pressure. When heart-failure develops, a whole series of changes take place in the intra-auricular and intraventricular pressure curves. In a patient with emphysema and heart-failure the pulmonary systolic pressure was raised to 68 mm. Hg, and in mitral stenosis with severe failure it was much higher —in one case it reached 103 mm. Hg, falling to 57 mm. Hg as the patient recovered from the failure. In other forms of heart-failure (hypertensive and arteriosclerotic) the pulmonary systolic pressure rises to 50–80 mm. Hg. Ordinary arterial hypertension without failure, however, does not affect the pressures on the right side of the heart, the pressure in the pulmonary artery remaining normal. By studying the pulse pressure and the amplitude of the auricular and ventricular pressure waves conclusions can be drawn regarding the changes in output per beat during the respiratory cycle[3] Inspiration assists the filling of the chambers of the right heart, so stroke output is increased; while during expiration the output of the right auricle and ventricle falls. In the early part of inspiration the increased output of the right ventricle is accommodated in the lungs, but a little later the left ventricle gets the increased flow and the systemic arterial pressure rises. This technique opens up new possibilities for the detailed analysis of human cardiodynamics in health and disease.

Proceeding along simpler lines of measurement of filling pressure and output per minute, Howarth, McMichael, and Sharpey-Schafer[4] at Hammersmith have continued their studies on heart-failure. They found that in "low output heart-failure" venesection lowers the venous pressure and raises the output of the heart. By comparison in similar groups of cases, they showed that lowering venous pressure by mechanical means and by digitalis have identical effects on cardiac output. Venesection, however, lowers the blood-pressure, while digitalis may leave it unchanged or even raised; so the heart is actually doing more work after digitalis than after venesection. Whether this can be interpreted as a stimulating action of digitalis on the heart is uncertain, but these studies seem to have established the importance of a primary reduction in venous pressure by means of digitalis in the treatment of the failing heart. Warren and others[5] have drawn attention to the possibility of errors in the estimation of cardiac output arising from incomplete mixing of blood in the right auricle. Duplicate samples taken in this situation were found to differ from one another in oxygen content by more than 0·4 vols. per cent. in a fifth of the cases studied. Similar studies by Cournand[6] showed, however, that the differences between duplicate samples from the right heart were very seldom more than 0·4 vols per cent. McMichael[7] thinks that anomalous samples are obtained only about once in 20 cases. Any error arising from incomplete mixing is readily detectable by comparing right ventricular with right auricular samples and by duplicate sampling at critical points in all experimental observations; if this is done the results obtained should be highly accurate, but isolated observations may be open to suspicion.

The catheter's potentialities as an instrument of investigation do not end at the heart. A catheter with an angle bend near the tip can be passed through the auricle into the inferior vena cava, and under fluoroscopic screen control it may be manipulated into the hepatic or renal veins. Bradley and his colleagues[8] have made quantitative studies of the hepatic blood-flow in man by an ingenious method Bromsulphthalein, a substance which is removed from the blood-stream by the liver, is infused into a vein at a rate equal to the rate of excretion, so that the blood-level remains constant. The concentration of bromsulphthalein in the blood entering the liver is taken to be the same as that in the peripheral blood, and by sampling the hepatic-vein blood the amount extracted from each 100 ml. can be estimated. A sample calculation may make this clear.

Rate of removal (or infusion) of bromsulphthalein = 4 80 mg./min.; peripheral serum concentration = 1 08 mg./100 ml.; hepatic vein serum level = 0·57 mg./100 ml, hæmatocrit = 43%.

$$\text{Estimated hepatic blood-flow} = \frac{4{\cdot}80 \times 100}{1{\cdot}08 - 0\ 57} \times \frac{100}{100-43}$$
$$= 1651 \text{ ml./min.}$$

A considerable range of values can be obtained in one subject—e.g., from 945 to 1618 ml /min.—according to the position of the catheter in the liver It is possible that the rate of flow does vary in different parts of the liver, and it is a slight drawback to the method that *mixed* hepatic-vein blood cannot be obtained. Bradley and his colleagues, and Warren

A large part of India's health campaign, in James's words, consists of "encouraging the will to be healthy, and spreading the knowledge of the meaning of health"; and wide circulation of his booklet will certainly help this aim. Nevertheless a health service, no matter how complete, cannot by itself solve India's health problem. Until there is a substantial rise in the standard of living people will continue to die of starvation and of the diseases attendant on malnutrition; the nutritional and dietary surveys by members of the Servants of India Society[2] emphasise this fact. These studies include accounts of famine conditions in Malabar, Madras, and Kanara, and contain many valuable family dietary surveys, which illustrate vividly the shortcomings of the typical Indian diet and the poverty of the Indian peasant. The curses of inadequate price control and of ineffective administrative measures are here translated into terms of mouthfuls of rice and morsels of meat and fish. The great volume of facts revealed by these painstaking studies underline the need for rigid control of the price and distribution of all foodstuffs, and not only the basic cereals. Stress is also laid on the need for irrigation and subsidies to encourage food-production. For India, at present, food is the best medicine.

COLDS AND CONSTITUTION

NEWS of the reopening of the laboratory's offensive against the common cold reawakens interest in the other means of studying civilised man's most persistent enemy. With so much clinical and epidemiological material on every hand, there is little excuse for any failure to extract all possible information from observations in the field. Yet opinion is still divided even on so simple a topic as whether some people catch colds more frequently than others.

A group of workers at Boston[3] endeavour to answer this query. Under the rather formidable title of Stability of Resistance to the Common Cold, they analyse the incidence of upper respiratory infections during four years among the boys at the Phillips Exeter Academy. Previous work at the Harvard School of Public Health[4] had suggested that the frequency of colds in individuals was not, as deduced by Gafafer and Doull,[5] explicable by the operation of the laws of chance, and the Exeter Academy study provides fresh evidence that each person has a relatively constant incidence; the number of colds each year seemed to be characteristic for the individual, and slightly increased as the investigation progressed from 1935 to 1939. Sargent and his associates deduce that some factor such as the constitution must play a significant part in determining the incidence of a disease which appears to be thus correlated with the individual host, but the value of their study is somewhat lessened by the inclusion of all cases of coryza, pharyngitis, laryngitis, bronchitis, tonsillitis, and even pneumonia under the heading of common colds, even though 95% of all cases were diagnosed as "nasopharyngitis." It is probable that epidemic influenza, for instance, was thereby included, and it would surely have been fairer to have used for such a mixture a term such as A.R.D. (acute respiratory disease), as adopted by the United States Army.[6]

The thesis that constitution affects the incidence of an acute infection is not new, and has been applied by several authors to poliomyelitis.[7,8] Constitutional factors which determine the incidence of disease could, of course, be genetic, as suggested by Webster's work on the inbreeding of mice,[9] or might depend on individual influences such as the hormones. Mention of hormones in connexion with the common cold reminds one of some remarkable and unexplained facts recorded by the School Epidemics Committee of the Medical Research Council.[10] Boston boys may develop colds by numbers, but the M.R.C. report suggests that British schoolgirls suffer from colds three or four times as frequently as their male coevals—though boys and girls suffer equally from influenza.

VITAL STATISTICS AND THE M.O.H.

IN discussing innovations in the methods of national vital statistics at the meeting of the Society of Medical Officers of Health on Feb. 20, Dr. Percy Stocks, medical officer to the Registrar-General's Office, described a morbidity survey of E.M.S. hospital patients. The hospital records were sampled and the main features of each of the 1 in 5 cases selected were transferred to punched cards. The populations exposed to risk could not be enumerated, but proportional rates based on the non-seasonal diseases gave some indication of the ebb and flow of serious illness, and some useful specific investigations were made on motor-cycle injuries and transfusion hepatitis. This experience will be valuable as a basis for a complete and accurate scheme of recording the clinical material in the National Health Service hospitals. A more novel kind of morbidity-sampling inquiry is being conducted by the governmental agency known as Social Survey. Here a statistically representative sample of the population numbering 2500 is selected each month. Each person is questioned about his health in the previous three months by a field worker. The refusal-rate is negligible, and Dr. Stocks was confident about the general accuracy of the results. When combined with the fuller notifications of infectious disease now in hand, the sample survey has much to commend it as an epidemiological tool for the M.O.H.

Mr. Louis Moss, director of Social Survey, said that the picture of the cross-section of the adult population given by the sample agrees with that obtained from the more usual national statistics, and the incidence of serious illness in the sample corresponds with estimates based on E.M.S. surveys. However, validation studies involving a clinical examination of a sample of those interviewed are under way. Later speakers, while appreciating the limitations and difficulties of morbidity surveys, agreed on their potential value to the M.O.H., when, freed by the new Act from other responsibilities, he can concentrate on the environmental aspects of sickness as well as death.

WHITE PENICILLIN

FROM the beginning of this year a "white" penicillin free from the impurities that gave the drug its yellow colour has been obtainable. White penicillin is sold at the price which yellow penicillin used to cost, while the less pure product is reduced to three-quarters of its original price—the lowest charge for penicillin anywhere in the world. The unitage of this white penicillin ranges from 1200 to over 1600 units per mg., but there can be no guarantee that brands of the same unitage will be equally effective therapeutically unless we know what proportions of the different penicillins the preparations contain. Thus white penicillin may contain from 10% to 30% of penicillin IV, which, from American evidence, is quickly inactivated by the human tissues and therefore of little therapeutic value. However, two of the principal producers claim that their products contain at least 90% of penicillin II, which is known to be active in vivo as well as in vitro against a wide range of bacteria. One of

Annotations

MEDICAL STAFFING OF HOSPITALS

WHAT medical staff does a hospital need for full efficiency? Prof. G. E. Gask, F.R.C.S., tackles this question in a memorandum to the Oxford and District Joint Hospitals Board.[1] He begins by collating information on the present staffing standards of various types of general hospital. At one extreme is the old poor-law ratio of one doctor to nearly 170 beds; at the other is a surgical professorial unit where there is one clinician for every 10. On theoretical grounds a standard of one doctor to 25 beds would, he believes, be insufficient for first-class service in a 1000-bed hospital, especially on the surgical side. Examining the staff structure of two first-class county (municipal) hospitals he finds the following proportions of medical staff to beds:

	St. Helier (Surrey)	Central Middlesex
Medical	1 : 28	1 : 48
Surgical	1 : 23·2	1 : 24
Obstetrics and Gynæcology	1 : 19·4	1 : 27

Taking into account pathologists, physiotherapists, and registrars, St. Helier has one medical officer to 18·2 beds and the Central Middlesex one to 28, but the inadequacy of the latter figure is recognised, and a further 14 additional house-officers are to be appointed as soon as possible, bringing the ratio to one to 19. This contrasts favourably with a borough hospital which has only three doctors for 600 beds (410 chronic).

After considering Stark Murray's estimate of one doctor to 18 beds (work including outpatients and domiciliary visits) and Robb-Smith's estimate of one to 12 beds (admittedly too high for the immediate future) Professor Gask concludes that the minimum standard for the recognition of a hospital as first class should be the allowance of one medical officer to 20 beds, or fifty to a 1000-bed hospital; but he regards this figure as low, and until the aim of one to 15 beds can be attained the doctors should have all the aid an efficient clerical and record department can give them. Ancillary workers are provided in many departments, but clinicians are too often expected to write their notes in long-hand, keep their own records, and follow up their own cases.

> "The formation of a first-class hospital cannot rest on a mere formula of power-mathematics. The staff of a good hospital must be professionally and spiritually contented. They should not be so driven by stress of work that they have no time to think, to study and to visit and confer with their professional brethren, both at home and abroad. Good hospitals should become 'seedplots of wisdom,' germinating ideas for promoting the positive health of the people as well as for curing disease."

Professor Gask's estimate of the medical staff required to maintain a first-class general hospital will be widely accepted by those familiar with the running of such a hospital; and it is well, even in these times of shortage, that the need should be known. By general consent, some 5 acute hospital beds per 1000 of the population (or 200,000 for England and Wales) are needed. These are not all available, nor are those that are available all suitable for their purpose. If they were, their full use would demand the whole-time service of some 10,000 doctors. Though the chronic, infectious, tuberculosis, and mental beds, which are also necessary for a complete hospital service (and which will amount in sum to nearly double the acute beds), may not want a staff ratio of this magnitude, it is all too evident that the adequate medical staffing of our hospitals is a problem as great as it is fundamental.

---

PARALDEHYDE ACCIDENTS

THE accidental deaths from paraldehyde poisoning, of which two more examples were reported in THE LANCET of Feb. 1 (p. 188), arise from two closely similar causes. In the latest cases there was confusion between pure paraldehyde and a dilute solution; in the case at Swindon in 1942, among others, there was confusion between the drachm and ounce signs. The second risk should be eliminated as the fluid drachm disappears from general use; the first has not yet received the attention it deserves. In many hospitals paraldehyde is stored in the wards or theatres both in the pure state (*B.P.* dose 60–120 minims) and in a dilute solution, termed "*haustus paraldehydi*" or "paraldehyde draught," the dose of which is usually 1 or 1½ fluid ounces, according to its strength. The draught is not an official preparation, and its use is one of the reasons for mistakes. The medical student (and hence the house-officer) and the nurse in training often fail to distinguish between a drug and a preparation of a drug. Thus many a young doctor or nurse would loosely call paraldehyde draught by the short name paraldehyde. And some never grow out of this habit. How many times has one heard the expression, "8 minims of morphine was given" when 8 minims of solution of morphine was meant? But here there is more excuse for muddles, because paraldehyde draught varies in different hospitals: in some it is a clear solution resembling paraldehyde itself; in others it has a layer of paraldehyde floating on a layer of water; while in yet others it contains liquid extract of liquorice and other ingredients which readily distinguish the draught by colour from the pure liquid. Surely if paraldehyde draught is required in the wards a uniform formula and a uniform and distinctive colouring should be adopted in all hospitals. It should be an invariable rule, too, that bottles containing either draught or pure substance must have the dose clearly stated on the label.

INDIA'S NECESSITY

Sir Frederick James[1] gives us an excellent popular exposition of the monumental report of the Bhore Committee, of which he was a member. Here in small compass are the essential facts about the health situation in India, written in language which everyone can understand.

Perhaps the most striking of these facts concern deficiencies in India's health personnel. Of the 47,400 doctors (one for every 6300 of the population) only 4000 are women, though only women doctors can hope to bring modern medicine to India's women and children. There are only 1000 qualified dental surgeons, 7000 trained nurses, and 75 pharmacists in the whole of British India. About half of the districts and three-quarters of the municipalities of British India have no qualified health officers. It is against the background of such deficiencies that the infant-mortality of 160 and the expectation of life of 27 years have to be considered. James does not, however, content himself with painting a grim picture; he also summarises the proposals which form the second volume of the Bhore report. These include the provision of a health centre for every 20,000 of the population, each 30 centres being grouped under a more specialised secondary unit, with a district headquarters for every 5 secondary units; 125 such headquarters, each serving a population of 3 million, would cover the whole of British India. The service planned would include public health and preventive medicine, and also home and hospital treatment. It is a surprise to read that the estimated cost of this scheme is only 3 rupees (4*s*. 6*d*.) per head per year for the first ten years.

adequate level for *Staph. aureus* and some strains of *Strep. fæcalis*. A dose of 200,000 units six-hourly would probably be lethal to most gram-positive organisms and about 50% of gram-negative bacilli. There is, however, wide individual variation in the levels obtained, and further work is required on this subject.

Another field for inquiry is the use of penicillin in the prevention of urinary infections. If the drug will prevent urethritis and ascending infection due to the indwelling catheter, one of the urologist's main difficulties will be overcome. Preliminary reports are encouraging.

New advances bring new problems. Thus, in specialist surgical units, where there are many similar cases, there is a danger of a penicillin-resistant strain being spread round by cross-infection unless the strictest precautions are taken; this must be borne in mind in urological wards. Another danger is that the removal of staphylococci from an infected area may lead to an increase in gram-negative contaminants. This may not greatly matter in surface wounds, but a heavy infection with insensitive proteus or *Ps. pyocyanea* might be serious in the urinary tract. It must also be remembered that in many urinary infections relapse will be inevitable unless the mechanical efficiency of the tract is restored by surgery.

OF NOT SMOKING

THE cost of tobacco imports this year is estimated at £50 million—a full £15 million more than the total for consumer goods and only £10 million less than the anticipated expenditure on machinery and equipment. Much of this tobacco comes from the United States; and the Government are said to have decided that, to conserve our dollar resources, the amount must be reduced. American growers are so confident of this cut that they have already scaled down their production plans.

If the cut were made, it could be argued that, tobacco being non-essential, ordinary private trade might be left to take its course, with the demand constantly exceeding the supply. Again, the tax might be increased until the demand came down to the level of the supply; here the objection is that any further imposition might make of smoking a pastime only for the rich. Again, rationing could be introduced, as on the Continent—a solution that would at least have the merit of tending to provide equal shares for all. Finally, what was lost from America might be made good by purchases from "soft-currency" countries: and Greece is said to have been marked as the source best able to make good the deficit.

It is not easy to gauge the priority which tobacco may justifiably be given. With essentials, such as food, our requirements can be assessed within narrow limits; while the morale value of luxuries, such as films, can also be judged with fair accuracy. Unfortunately, there is no yardstick for the measurement of tobacco's virtues. Hitherto authority has pandered to the growing national taste for a smoke; all through the war the country had as much, or almost as much, as it demanded; and there is little doubt that any restriction now would be violently opposed. Tobacco is, in fact, commonly regarded as an essential comfort, though why it should occupy this place in our affections is not clear. Plainly, smoking has not, as some have supposed, simply a symbolic value; for the chewing of gum, though better than none, is a poor substitute. Nor is its effect wholly explained by its pharmacological action. It seems likely that the comfort it brings is derived, as with alcohol, from a complex of conditions which defy rational analysis. Empirically, there is no doubt of its capacity to allay anxiety: the enhanced demand during the war was probably related less to increased spending-power than to the troubled times. For a great many people smoking has become a means of keeping a mild psychiatric disability within bounds, and we must face the fact that any sudden or drastic reduction in supplies of tobacco would cause a sharp rise in the incidence of overt anxiety.

LIGUE INTERNATIONALE CONTRE LE RHUMATISME

THIS body has been reconstituted, under the presidency of Dr. Ralph Pemberton, of Philadelphia, and has been subdivided into a European Ligue and an American Ligue. A European congress will be held in Copenhagen next September and an international congress in the United States in 1949. The British branch of the Ligue is represented by the scientific advisory committee of the Empire Rheumatism Council, with Dr. W. S. C. Copeman as chairman and national representative, Dr. G. D. Kersley as treasurer, and Dr. Oswald Savage as secretary. New members will be welcome, and particulars may be had from the organising secretary, Empire Rheumatism Council, Tavistock House North, Tavistock Square, London, W.C.1.

SMALLPOX

IN the Grimsby outbreak, where infection occurred in a lodging-house for seamen and farm labourers, the number of cases up to March 11 was 15, and 6 of these patients have died. All secondary cases have occurred in the direct line of contact. At least 8 contacts in this outbreak are still at large and remain unidentified.

A case of semiconfluent smallpox has now been reported in a man of 66 years, a resident member of the staff of the Empire Memorial Hostel for Seamen, in Commercial Road, Stepney. No direct connexion with the Grimsby cases has been established. This man sickened on March 3, and was removed to Mile End Hospital (L.C.C.) on the 5th. He remained there until the 9th, when he was removed to a smallpox hospital. The Ministry of Health recommends that people who visited the seamen's hostel between March 2 and 6 should be under careful surveillance until March 20, and any person who has visited the hostel since Feb. 14 should be medically examined. The source of the infection in Stepney has not yet been identified, and it is assumed that an abortive or ambulant case—probably a woman—is still at large.

Several cases of smallpox have lately been reported in Paris, and the outbreak is expected to spread.

RELEASE OF DOCTORS FROM SERVICES

THE Central Medical War Committee have been informed that the release of medical officers in class A will be as follows:

Royal Navy.—April, group 60: May and June, group 61.

Army.—*General-duty Medical Officers*: April, group 57; May, group 58; June, group 59. *Specialists*: April 1–20, group 45; April 21–May 11, group 46; May 12–25, group 47; May 26–June 4, group 48; June 5–15, group 49; June 16–30, group 50.

Royal Air Force.—April, group 58.

WE regret to report that Dr. B. A. MCSWINEY, F.R.S., dean of the medical school and professor of physiology at St. Thomas's Hospital, died on March 8 at the age of 52.

WE have also to record the death of Dr. LOUIS COBBETT, a former professor of pathology in the University of Sheffield and lecturer in pathology in the University of Cambridge, who died on March 10. Since his retirement in 1929 Dr. Cobbett had continued his work on the bacteriology of tuberculosis. He was 85 years of age.

THE INDEX and title-page to Vol. II, 1946, which was completed with THE LANCET of Dec. 28, is published with our present issue. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam Street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive indexes regularly as published should do so now.

these preparations is a crystalline sodium salt of penicillin which is said to withstand high temperatures for long periods without deterioration. In addition to their greater stability the purified penicillins should be less liable to cause painful or allergic reactions or to irritate delicate tissues like the meninges and the conjunctiva, while highly concentrated solutions of say a million units per c.cm. can be used for parenteral injection. The need now is for some amendment of the regulations under the *Therapeutic Substances Act* to ensure that these purified penicillins are as effective in the host's tissues as they are in the test-tube.

FEEDING THE LONELY ADULT

THE fact that there has been no obvious deterioration in the national health in the past seven difficult years has made most of us feel that our nutritional policy is basically sound. Even the rationing of bread—the most serious step which has been taken in determining the consumption of food—aroused no serious objections on nutritional grounds. In conformity with the Ministry's usual plan of adjusting the rations roughly in accordance with nutritional needs, manual workers and adolescents receive more than the standard adult ration of 9 oz. of bread daily, while children under five receive less. Children between five and eleven receive the same as a normal adult. Many children do not consume the whole of their ration—for example, the child of six does not usually consume as much as 9 oz. of bread in one day, nor a child of two as much as 5 oz. Thus, the adults in a family with children can often benefit from the children's ration of bread, as they also no doubt benefit from their ration of tea and to a lesser extent meat and cheese. On the other hand, the children probably receive more than their share of eggs, jam, and sugar. There is thus a redistribution of food within the family which is a great help in feeding its members. The study of Schulz [1] in Oxford suggests that the extent to which adults can practise "symbiosis" with their children may determine the total adequacy of their diet. In a series of papers published at six-month intervals, beginning in the spring of 1941, Schulz has devised low-cost diets obtainable by an Oxford family of two adults and three children. In the last two papers she has included a reasonable distribution of the food within the family to meet accepted dietary habits as well as nutritional needs. For example, the adults are allotted appreciably more than their ration of bread, bacon, and cheese. The striking fact which emerges from Schulz's last paper is that, with bread rationed, a distribution within the family which is to give sufficient calories for the adults must involve a diversion of rationed foods from the children. In the diets suggested by Schulz, this diversion is equivalent to some 9 points or bread units weekly to the two adults.

How do adults fare who are living alone and therefore denied the advantages of family distribution? It appears from Schulz's paper to be impossible, with bread rationed, for such people to obtain enough calories with reasonable ease and at reasonable cost. They must either consume unappetisingly large quantities of unrationed foods which supply a fair number of calories (for example, something like 4 lb. of potatoes daily for each adult) or they must take a meal out on most days of the week. Meals out are not always practicable and would raise the cost of the diet appreciably, though British Restaurants and works canteens have done much to overcome these obstacles. There remains a third possibility—the consumption of much more expensive unrationed foods, such as ready-cooked pies or sandwiches. But this would raise the cost still more and is not considered by Schulz, who is concerned only with low-cost diets. The difficulty of providing adequate adult diets at low cost, where neither meals out nor children's rations can be drawn on, did not arise so long as bread was unrationed. But that it now exists can be confirmed by anyone with a knowledge of present-day food-supplies, and the patience to spend tedious hours with a set of food tables and a slide-rule.

PENICILLIN IN URINARY INFECTIONS

WE have become accustomed to think that penicillin is of little value in infections of the urinary tract, since most of the common infectors are either gram-negative or belong to the less sensitive gram-positive groups. The value of penicillin in *Staph. aureus* perinephritis, and in association with surgery in renal abscess and stone, is well known. At the Royal Society of Medicine, section of urology, on Feb. 27 Mr. A. L. Peeney drew attention to the possibility of using the drug to control the other more common, but less sensitive, infections due to *Strep fæcalis*, *Proteus morgani* and *vulgaris*, *Bact. coli*, and *Ps. pyocyanea*. He finds, in common with Helmholz and Sung,[1] that many of these organisms are sensitive to high concentrations of penicillin. Of 199 strains isolated from urinary cultures (see table), 132 (66%) were killed by urinary concentrations below 200 units of penicillin per c.cm. Most strains of *Staph. pyogenes* are killed by a urinary concentration of 0·03 unit/c.cm., but other gram-positive organisms may require a concentration up to 10 units/c.cm., and the gram-negative bacilli up to 200 units/c.cm. *Ps. pyocyanea* is entirely insensitive up to this level.

MINIMUM BACTERIOSTATIC CONCENTRATIONS IN 199 STRAINS OBTAINED FROM URINARY CULTURES

Organism	Total strains	Penicillin units per c.cm. urine > 200	200–100	100–50	50–10	10–0·5	< 0·5
Staph. pyogenes	33	2	..	..	2	..	29
Strep viridans	8	..	..	..	..	..	8
Strep. fæcalis	22	..	..	..	..	22	..
Coliforms	81	32	20	21	7	1	..
Proteus morgani	24	16	1	..	6	1	..
Proteus vulgaris	18	4	2	1	5	6	..
Ps. pyocyanea	13	13	..	..	..	..	..

The courses of penicillin adopted in urinary infections have clearly been far too low in dosage and far too short. Routine estimations of the urinary concentration are usually not feasible, and it is therefore important to know what scale of dosage can be relied on to produce an effective concentration. Furthermore, since these dosages may have to be continued for a long time, and possibly for conditions which in themselves are not painful, the method of administration chosen should not be too unpleasant. The oral route, which could be used in outpatients, would be ideal. Unfortunately, however, Sir Howard Florey told the section of urology that when enteric-coated capsules are given by mouth only 8–23% of the penicillin administered is secreted in the urine, compared to 33% after beeswax and peanut-oil injection, and 65–80% after injection of saline solutions. Peeney, using salol-coated capsules, found that combination with a slow-release vehicle is no advantage. Using ordinary penicillin (90,000 units) in these capsules he obtained urinary concentrations of 40 units/c.cm., but these fell rapidly in spite of further three-hourly doses of 20,000 units and reached 10 units/c.cm. in twelve hours. After a single intramuscular injection of 100,000 units of penicillin in saline the urine (50 c.cm.) at one hour contained 680 units/c.cm.; bulked urine between three and four and a half hours after injection (608 c.cm.) contained 85 units/c.cm.; and at eight hours (132 c.cm.) still contained 2·6 units/c.cm. This is an power and the other resources proportionate to our national need, we are pursuing the opposite policy. We have devised an elaborate system of artificial restriction of the price of food partly compensated by subsidies to the producer. It would take us too far afield to discuss in detail the effect of subsidies on the amount of food produced, but it may be observed that subsidies do no more than partially make up to the producer with one hand what the State has taken away with the other—the opportunity to sell his produce at prices regulated by supply and demand. Imports are a national luxury when the means of paying for them no longer exist; yet not only do we accept them on credit, but we allow them directly or indirectly to dictate the level of food prices at home.

---

[1] Schulz, T. *Bull. Oxfd Univ. Inst. Stat.* 1946, 8, 375.

[1] Helmholz, H. F., Sung, C *Amer. J. Dis. Child.* 1944, 68, 236.

A simple example will help to bring out the point. Let us take the case of a crop where effort is directly determined by price: that of potatoes grown in gardens and allotments. At the present controlled price at which the individual can buy potatoes (10*s.* a sack), it is not worth while either to employ one's own energies in the production of potatoes or to employ labour for the purpose. Were the price of food allowed to find its true economic level the price of potatoes would rise by a multiple of probably two to three times, and it would at once become advantageous to some millions of persons to grow their own potatoes. To suggest that such an action would be a waste of national energy, since potatoes can be purchased cheaply, is no answer in present circumstances, and is to drag in the assumptions of a world of free trade which no longer exists. The point on which attention should now be concentrated is that the country simply has not got the available exports with which to buy food of a kind which can be produced at home.

DEAR FOOD ?

The necessary long-term adjustment of the price-level of food relative to other goods does of course present difficulty. It involves abandoning conceptions which in the course of a century and a half have become fixed in our minds. There are, however, various ways by which the disturbances which such an adjustment would inevitably cause might be rendered bearable, and its dislocating effect upon the low-income groups be mitigated. What this article is meant to stress is the fact that the crisis which confronts us today can be remedied only by setting clearly before us the goal which a straight reading of our economic situation dictates—a major upward adjustment of the price-level of home produce in relation to the price-level of other commodities.

Frenzied efforts to capture an evanescent export market involve a further dislocation of our economy in precisely the wrong direction. Let us by all means export all we can; let us by all means take advantage of the "sellers' market" now open; but let us keep our eyes open and cease to obscure the fundamental tendencies to which we must in the long run conform. It is juggling with food subsidies, price-levels, and imports purchased on credit that is blinding us and leading us to real disaster.

A FALL IN THE STANDARD OF LIVING ?

It looks as though, sooner or later, we shall have to dispense with those imports, chiefly food, which we can produce at home if we devote to them a sufficient proportion of our productive resources. To adjust our economy in this way would involve a doubling—or perhaps even more—of the man-power and other resources allocated to agriculture and certain other allied occupations. It would involve too a sharp rise in the price of food, bread alone perhaps excepted. Prices of all other food may have to rise to something like twice their present proportion of the ordinary householder's budget.

Does this mean that we must face a fall in the real standard of living as compared with pre-war days? The present Government propaganda, backed by all the powerful industrial interests with a stake in the export market, asks us to believe that such a state of affairs is a dark abyss which we dare not contemplate. It is surely nothing of the kind. Let us look at the items of debit and credit in turn.

DEBIT AND CREDIT

The two chief debit items which must be faced are (1) the difficulty of adjusting the internal price-level for agricultural produce as contrasted with other consumer goods; and (2) the immediate check to industrial expansion in so far as it depends upon an expanded export market. Both of these effects, however, are transitory, and both would cease to be noticeable in a relatively brief period, perhaps 3–5 years. The effect of the check on the export industries should not be exaggerated, since by far the greater part of the excess exports of today over 1938 levels is of goods for which there is a home market already strained to the breaking-point by the divergence between demand and supply.

The items on the credit side of the account are surely of far greater consequence. Let us start with the simpler points.

First, by inviting an increased flow of man-power into agriculture we at once check and reverse many of the tendencies towards urbanisation which are themselves one of the great social problems of our time.

Second, we begin to release for the home market the productive capacity of our export industries. Do not let us forget that our present forced-exports policy can really promise little or nothing in this direction: we are told to wait till tomorrow or the next day, but there is no solid assurance that in 3 or 5 years' time the export balance will have been attained.

Third, by substituting a moderate export policy for a forced one we achieve a far greater degree of national independence; and, to the extent that we set employment at home free from the vagaries of political and other circumstances abroad, we improve our bargaining position. The state of the world is today such that nothing but the present panic about our export balance would blind us to the importance of this objective. It is linked with the fourth item on the credit side—the advantage the policy offers of enabling us to proceed without "direction" with our programme of social justice upon which all parties are at heart agreed.

EXPORT DRIVE AND DIRECTION OF LABOUR

This last point is of great significance and deserves to be closely considered. The present forced-exports policy carries with it the necessity for man-power for the export industries, but the need to sell abroad forbids any real elasticity in the wage-rates offered. This fact underlies the present "shortage of man-power"; what the outcry really means is that whereas it is notorious that many distributive and luxury trades can secure the man-power they require, the export trades, and certain other basic industries like coal-production whose costs affect the export market, are finding themselves gravely short of man-power. The Government are at present at the stage of trying moral suasion; but it is not surprising that we hear whispers of the necessity for direction. It is indeed the next step, and if the Government are driven to it our liberty will be gone, and socialism will have sold its birthright.

There is only one way of avoiding this impasse—by building our internal economy on foundations which permit of a free play of incentive and reward as between the various occupations. It must be possible for more man-power going into one industry to be compensated by less going into another, and in this vital respect we must return to the elasticity of the old economic system. Such an economy is not incompatible with socialism; but it is hopelessly incompatible with a policy of forced

Reconstruction

THE NATIONAL SITUATION

Exports and Agriculture

FROM A CORRESPONDENT

The Government are now so convinced of the doctrine "export or starve" that it seems almost disloyal to cast doubt on the economics on which it is based. Yet neither the Government spokesmen nor the economists have so far advanced any substantial arguments to justify their belief in the course on which we are embarked.

Clearly there is need for a major change in the basis of our national economy if we are to survive; but the first essential is to determine our goal in the broad context of our economic history. A slight knowledge of the past is sufficient to raise uncomfortable doubts whether we are now heading in the right direction.

As every schoolboy knows, the export trade of the 19th century was built up on the manufacturing capacity of Great Britain. We had led the way in the industrial revolution, and the rest of the world was glad of our products. With the proceeds and the help of our exports of coal we were able to buy our imports of food and raw materials. But as the years passed, and at a quickening tempo during the last few decades, the rest of the world has learned to manufacture for itself. Before the war it was widely understood that the market for our exports was steadily contracting, though the effects were often masked by the rapidity of technical advance and our ability to switch from one export to another. In 1938 the position was, in round figures, that our net retained imports amounted to £857 million, including £385 million for food, while our exports stood at £470 million. The balance we made good with the income from foreign investments, and with our invisible exports.

It is this balance which has largely disappeared, and on which so much emphasis is placed today. If exports could be doubled, all would be well; but there is surely no solid ground for supposing that once the pent-up demand created by the war has been exhausted the underlying tendency to contract will fail to reassert itself. The Government have assured us that there is no danger of over-production for a long time to come; and so far as this goes it is a comforting statement. But does it not conceal an element of wishful thinking? Of course the rest of the world whose economy is almost as badly shaken as our own would like to buy all sorts of things today; but others too are trying to set their houses in order, and before long we shall surely encounter the old desire to manufacture for themselves. In some industries this will come soon, in others it may be long delayed; but the principle stands. And if exports settle down again at our pre-war level we shall indeed be stranded.

The decision lies finally not with our workers or their output—though these are of course important factors—but with the politicians of the world at large; and the world will take our exports only to the extent that suits its convenience. Gradually a new world of freer trade may emerge, but not in the next two or three critical decades.

FOOD AND ITS PRICE

What then? Let us proceed for a moment on the assumption that the above diagnosis is correct. Shall we starve? *It is not enough to answer automatically Yes;* we must look more closely at the age-old mechanism of supply and demand and its monetary consequences.

What really happened under the régime of the 19th century was that Great Britain was enabled by her advantage in manufactures to devote a relatively small part of her energy to the production of food. In the old phraseology, our exports enabled us to buy food abroad at a price below that at which we could produce it at home. So long as free trade endured, the price of food was bound to remain low. But with the whittling away of free trade, and now with its virtual disappearance, a new situation has arisen of which too little account has been taken. We have not got the means to pay. The whole of the proceeds of our exports are needed for obtaining goods, chiefly raw materials, which we cannot in any circumstances produce at home. The position is obscured by the readiness of other countries to send us foodstuffs at prices lower than those at which we can produce them in sufficient quantities. Since, however, those countries are unwilling to admit freely our manufactured goods, and the other half of the free-trade equation has fallen away, the low price at which we can obtain imports from abroad has become meaningless, for the simple reason that we cannot get them save by running into debt.

The remedy is a great increase in the production of food at home, and our war-time experience shows that this is within the realm of practical politics. In the war years we achieved an increase of 35% in our food-production, and this with the very limited man-power of war-time. With peace-time facilities, our production could certainly go much higher still, and, with the exception of wheat, approximate to 100%. (The importance of the bill for imported wheat should not be over-emphasised: grain and flour cost us in 1938 only £55 million out of a total import bill of £857 million.) What prevents this increase of production? One thing alone, the price-level.

The corrective to the situation outlined above is a sharp rise in the price of food at home. Food should tend to occupy an increasingly important relative position in our home economy. Higher prices for agricultural products would mean higher wages and more man-power—in other words a greater call upon our national productive capacity. If this simply corrective mechanism of supply and demand were allowed to operate today, a significant and probably dramatic rise in our food-production would quickly follow. If this sounds too good to be true, it is because the idea that Great Britain is a country dependent on food from abroad—the industrial millions and the bread to sustain them from abroad—has become a fixed idea. It is an idea based on the assumption that we must continue for ever to fix the price of food at home at a level determined by imports from the food-exporting countries. Yet if we care to pay the price in terms of national energy, we can expect an increase in our food-production vastly greater than that of our war-time effort with its limited man-power. We might in fact come well within sight of the total which in 1938 we imported from abroad; and our old 1938 level of exports would suffice very roughly to pay for the balance of the necessary foodstuffs, raw materials for industry, and other essential imports.

It will be at once objected that a substantial rise in the price of food at home is out of the question, that it would mean a rise in the cost of living, and that this would in turn damage the export trade. But this little group of arguments is full of fallacies, and must be abandoned once we accept the full implications of the argument so far followed. *A rise in the cost of living?* If it means that a greater proportion of the household budget would have to be spent on food, it is true; but that is not the whole story, for the policy also holds out the prospect of an easing of the drive for exports with its pressure upon the supply of consumer goods for the home market. Thus higher prices for food would be balanced by a tendency towards lower prices for many other consumer goods. Damage to the export trade? To argue so is to put the cart before the horse. If the export trade is likely to run into heavy weather and lead us into an impasse, is it right to argue that the only possible corrective process must be abandoned because it would hamper the export trade?

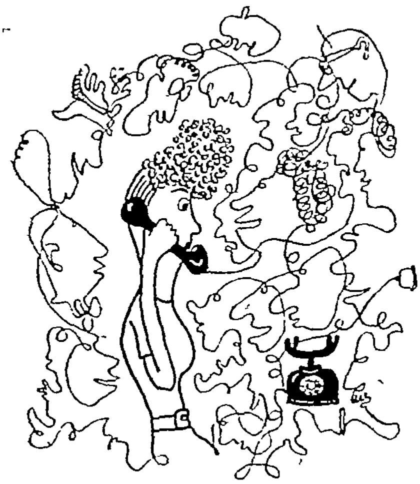
BUYING WHAT WE CAN PRODUCE

So far from allowing the internal level of the price of home-produced food to rise until it commands man-

In England Now

A Running Commentary by Peripatetic Correspondents

I HAVE often thought that a handbook for prospective wives of G.P.s would be worth publishing. Each chapter would deal with some aspect of the life, and at the end the candidate ought to be able to decide whether the game was worth the candle. I haven't time to write the book but I propose to dash off a few concise notes while the doctor is out on his rounds. They are not intended to be read by the minute percentage of doctors' wives-to-be who expect to spend the early years of marriage surrounded by nannies, maids, cooks, gardeners, chauffeurs, and secretaries, but by the austerity bride who will have to give up the dining-room in her villa for use as a consulting-room and strive to keep down expenses and maintain morale by looking after the children, the house, the meals, the garden, the patients, the telephone, the back door, the front door, and above all the doctor, practically single-handed.



Let us start with *The Telephone and How to Deal With It.*

One is warned as a bride of the dangers of living with relations, but the phone is a far more exacting companion than any mother-in-law—one can at least leave the good lady to look after the babies. The instrument is magnetic for children. I shall not forget trotting in from the garden one afternoon to answer it only to find my four-year-old standing on the chair and lisping into the mouthpiece: "My doctor will be back at ten-thirty." She replaced the receiver as I reached her. The call was urgent. Her daddy was asleep in a deck-chair.

If you have only one instrument put it in the kitchen near a comfortable chair by a table with a packet of digestive and alkali tablets thereon. (It is worth while finding out whether you have hyper- or hypo-acidity.) Have a line laid to every room with a plug and switch for connecting (and particularly disconnecting) the thing. If you can afford only one extension line have it laid to the w.c. At meal-times always go to the phone with your mouth full. It is more convincing. If your man hasn't a microphone manner like Stuart Hibberd it is better to answer the call yourself; better for the practice, I mean. Always gain the upper hand by asking more questions than the caller. This is more soothing for you both and transfers some of the responsibility to the caller. Get the facts. Truth is stranger than fiction and safer than friction. If caught cooking, turn off all gas and electricity before answering the call; an extra call after dinner is better than a burnt offering for a meal. If you hear nothing on lifting the receiver, shout loudly "Press button A!" Your voice must carry over the traffic. Then listen carefully. Country people do not willingly waste tuppence to tamper with infernal machines. Sweetening is vital when dealing with supervisors, but the men on at night are usually dears. When it's woman to woman you will know how to cope, sister. You will soon find that one of the most infuriating questions is "When will the doctor be here?" The correct answer is only learnt after hours of practice understudying B.B.C. actors. The answer comes with a light, broken laugh mixed in with this phrase: "Well—sometime——I hope."

How to deal with what you know to be an unwanted call: *You*, "I'm sorry, he's out." *Caller*, "When'll he be in?" *You*, "I don't know." *Caller*, "Can you . . . ?" *You*, "I'm going out." *Caller*, "I really wanted to speak to him personally. It's er . . ." *You*, "Can I take a message?" *Caller*, "Well, not really . . . I . . ." *You*, "Then will you ring at midnight? He'll be in then. There's a baby on the way." (There is one born every minute.) *Caller*, "I see, well, er . . ." *You*, "The milk's boiling over. Goodbye." A final word: don't use the blockage gambits such as "The doctor is just (having a bath, in a snowdrift, the lavatory, the chemist's, town, &c., &c.)." They won't work and he'll never remember the alibi anyway.

My finest hour was when the firstborn of the night supervisor at the local exchange was being delivered. Tied to his post of duty, he rang me up every so often to find out if the doctor was back, saying, "It's so nice to have someone to talk to at a time like this. . . ."

* * *

Our penchant for collecting lamps, antique and otherwise, from the ships in which we serve, ensured that we had two lamps in commission in our temporary house when the "Save-the-Transformers" cut followed close on the "Forbidden Period." A fine swinging model in our country kitchen suggested the roll of the ship and the creak of the timbers, and a table-lamp transformed the dining-room to a Nelson cabin. The problem was candles for stairways and bedrooms. The graceful Nell Gwynns, like the dressing-table candlesticks, were still not unpacked; but we had been using Gurr's embedding paraffin wax (remaining from my pre-war laboratory) to coax morning fires, so at least we had the raw material, and the wax melted quickly in a jam-jar on the hearth. Two tumblers in a basin of cold water, with a string wick hanging centrally from covering pieces of cardboard, were the first moulds. The next refinement was a wick of cut taper, inserted during cooling *au moment critique*; but a corkscrew wick was the reward of the tiro. The result at the end of an hour was : candles, 3 ; tumblers, 1. The final products had but a faint resemblance to the ecclesiastical species.

Did you know that there is a subtle relationship between the number of wick fibres and the diameter of the periparaffinium? This proportion was not quite right in my giant night-lights—so to the manufactory once more, this time to attempt a carriage-candle. I can now produce a carriage-candle such as they turn out tailor-made from a mould. I use a quarto sheet of paper, rolled to a tube and closed at one end, filled with melted wax and then cooled in water in a quart milk-bottle, and William Tell has nothing on my central placing of the taper. I might even consider accepting honorary membership of the candlemakers' union.

* * *

All this talk about dangerous drugs being stolen from doctors' cars conjures up painful pictures in the layman's mind of small boys chewing phenobarbitone tablets by mistake for acid-drops. The actual risk of any harm being done is very small indeed—so far as I know there has never been a death from this cause—but the average member of the public doesn't see it that way. When he hears one of the periodical announcements on the wireless his immediate reaction is one of righteous indignation. "Why the blazes can't these doctors look after their darned drugs? They're always leaving their stuff about. They ought to be prosecuted . . ." and so on, and so forth. There is only one certain protection: never to leave any case, parcel, bag, or other package containing dangerous drugs in one's car unattended. It is a beastly nuisance having to remember such details when one is busy with more important matters. But all this gets the profession a bad name. If a doctor likes to take a chance with his rugs or even his instruments, that is his affair. But when it comes to dangerous drugs I'm afraid it is a public duty to be careful. While there are sneak-thieves about we shall have to carry as few drugs about as possible, and either carry them in a pocket case or lug our bag into every patient's house. There seems to be no alternative.

* * *

It was good to receive my *Lancet* again; to tear off the wrapper, and throw it in its accustomed ball to the cat; and to go back with a click to the pleasant routine of early February. Thank you, Mr. Shinwell!

exports, where wage-rates become fixed by the necessity to sell goods abroad. Socialism as understood in this country implies an economy in which man-power is distributed among the different occupations according to the free choice of the individual, and not according to the will of an authoritarian State; and that means that each industry must be free to expand or contract in accordance with the demand for its products or services measured in terms of a price-level free to move up or down.

Need we then refuse to face the implications of the policy here advocated on the ground of its effects upon our standard of living? The answer is surely No: it offers the only course which will not carry us straight towards both the dictator State and an economic disaster.

SOCIAL OBJECTIVES

A word must be added in regard to the new meaning of the phrase "standard of living."

It happens that the economic crisis due to the loss of our foreign assets has coincided with the first serious attempt in this country to control the economic machine, and to put social objectives above purely economic objectives. The country has decided to put steady employment above private profit; to put a fair share of the necessities of life for all above the unrestricted distribution of the days of laissez-faire; and so on. It has in fact decided—and we are not likely to go back in this—to make a great change in the conception of "standard of living." It is not practical politics to embark on a programme of social justice and to judge the results by the purely material formula devised by the economists of a generation since. The sooner this is recognised the better; and our Government today, by accepting the view that failure to achieve a pre-war "standard of living" would amount to disaster, are doing themselves less than justice.

Medicine and the Law

"Wilful Refusal" to Consummate Marriage

HOWEVER simply a parliamentary draftsman may frame an enactment, some difficulty may be expected in its application. What could be clearer than these words in section 7 of the Matrimonial Causes Act, 1937 (for which Sir Alan Herbert, that master of the written word, had some responsibility)—"A marriage shall be voidable on the ground that the marriage has not been consummated owing to the wilful refusal of the respondent to consummate the marriage"? What is consummation? What is wilful refusal? One question was answered in 1945 in Cowen *v.* Cowen. The other is answered, subject to the final opinion of the House of Lords, in the recent case of Baxter *v.* Baxter.

In the Cowen case (*Lancet*, 1945, ii, 183) the parties agreed, as their married life began in the Persian Gulf where hospitals were not yet air-conditioned and where, as they believed, childbearing would be dangerous for a European woman, to practise contraception. The husband used a rubber sheath; later he practised coitus interruptus. Subsequently, when the element of danger to the wife from childbirth no longer existed, he continued to insist upon contraceptive methods. She begged him to lead a normal married life and allow her the chance of motherhood. He refused to change his course and he left her. She petitioned for annulment of the marriage under section 7. Mr. Justice Pilcher felt obliged to hold that complete penetration must amount to consummation. His decision was reversed.

"We are of opinion," said the Court of Appeal, "that sexual intercourse cannot be said to be complete when a husband deliberately discontinues the act of intercourse before it has reached its natural termination or when he artificially prevents that natural termination, which is the passage of the male seed into the body of the woman. To hold otherwise would be to affirm that a marriage is consummated by an act so performed that one of the principal ends, if not the principal end, of marriage is intentionally frustrated."

The court held that the husband had wilfully refused consummation; the wife was awarded her decree of nullity. Baxter *v.* Baxter was, in a sense, the converse case. The wife firmly refused to have a child, and her parents supported her in that determination. Throughout their married life she declined to allow her husband to have intercourse with her unless he took the precaution of using a contraceptive. According to the Cowen decision she had wilfully refused consummation. The husband, however, had to establish that the non-consummation was due to her wilful refusal. This he failed to do. The trial judge found that the non-consummation was due rather to the husband's own action in acceding to his wife's "request"; he had not made an attempt to have intercourse without contraceptives. Whether it was the request or the demand or the insistence of the wife, the husband was not entitled to the annulment of the marriage if he had acquiesced in the wife's requirements. In such a case, said the Court of Appeal, the husband would not be entitled to say that the wife had been guilty of wilful refusal within the meaning of section 7 until at least he had unsuccessfully brought to bear "such tact, persuasion and encouragement as an ordinary husband would use in the circumstances." The husband had acquiesced, though no doubt reluctantly, in the conditions imposed by his wife. "A reluctant acquiescence is nevertheless an acquiescence."

The Baxter petition, like the Cowen petition, was undefended. The King's Proctor was asked by the court, in view of the importance of the questions involved, to instruct counsel to argue in support of the trial judge's decision. The Court of Appeal upheld that decision and dismissed the husband's appeal, though leave was granted for the case to be taken to the House of Lords. It will be of interest to see how far the supreme appellate tribunal can discourage an impression that the "weaker sex" has the less difficulty in rebutting the allegation of acquiescence. In the Cowen case counsel who addressed the Court of Appeal as *amicus curiæ* suggested that the wife's conduct, if it amounted to acquiescence, might bar her from judicial relief. The judges, however, accepted the explanation of the origin of her consent to her husband's refusal of free intercourse and took into account her subsequent attempts to change his mind. In both cases the Court of Appeal declared that judicial decision must depend on the facts proved.

Public Health

Infectious Disease in England and Wales

WEEK ENDED MARCH 1

Notifications.—Smallpox, 5; scarlet fever, 1167; whooping-cough, 2290; diphtheria, 186; paratyphoid, 0; typhoid, 5; measles (excluding rubella), 13,337; pneumonia (primary or influenzal), 981; cerebrospinal fever, 71; poliomyelitis, 8; polioencephalitis, 2; encephalitis lethargica, 2; dysentery, 92; puerperal pyrexia, 109; ophthalmia neonatorum, 67. No case of cholera, plague, or typhus was notified during the week.

The 5 cases of smallpox were notified at Grimsby (see p. 339).

Deaths.—In 126 great towns there were no deaths from enteric fever, 2 (0) from scarlet fever, 5 (1) from diphtheria, 25 (0) from measles, 15 (0) from whooping-cough, 83 (12) from diarrhœa and enteritis under two years, and 121 (32) from influenza. *The figures in parentheses are those for London itself.*

The number of stillbirths notified during the week was 300 (corresponding to a rate of 28 per thousand total births), including 42 in London.

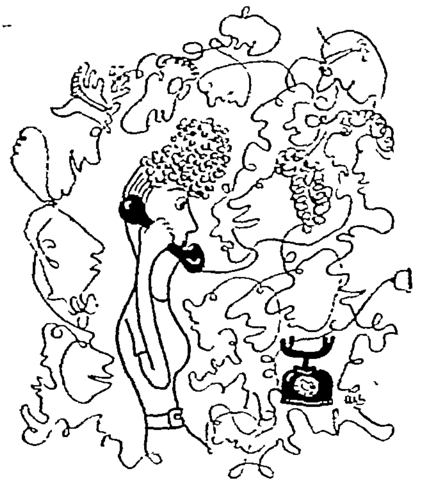
Winter in Scotland

During the long cold spell Scotland seems to have had less sickness than usual for the time of year. This view was given to a press conference on Feb. 28 by Sir Andrew Davidson, chief medical officer of the Department of Health, who added that three or four weeks previously children's ailments had threatened to be heavy but then died down as the weather became colder. Practitioners, he said, described the people as "miserable, but not ill."

In England Now

A Running Commentary by Peripatetic Correspondents

I HAVE often thought that a handbook for prospective wives of G.P.s would be worth publishing. Each chapter would deal with some aspect of the life, and at the end the candidate ought to be able to decide whether the game was worth the candle. I haven't time to write the book but I propose to dash off a few concise notes while the doctor is out on his rounds. They are not intended to be read by the minute percentage of doctors' wives-to-be who expect to spend the early years of marriage surrounded by nannies, maids, cooks, gardeners, chauffeurs, and secretaries, but by the austerity bride who will have to give up the dining-room in her villa for use as a consulting-room and strive to keep down expenses and maintain morale by looking after the children, the house, the meals, the garden, the patients, the telephone, the back door, the front door, and above all the doctor, practically single-handed.



Let us start with *The Telephone and How to Deal With It.*

One is warned as a bride of the dangers of living with relations, but the phone is a far more exacting companion than any mother-in-law—one can at least leave the good lady to look after the babies. The instrument is magnetic for children. I shall not forget trotting in from the garden one afternoon to answer it only to find my four-year-old standing on the chair and lisping into the mouthpiece: "My doctor will be back at ten-thirty." She replaced the receiver as I reached her. The call was urgent. Her daddy was asleep in a deck-chair.

If you have only one instrument put it in the kitchen near a comfortable chair by a table with a packet of digestive and alkali tablets thereon. (It is worth while finding out whether you have hyper- or hypo-acidity.) Have a line laid to every room with a plug and switch for connecting (and particularly disconnecting) the thing. If you can afford only one extension line have it laid to the w.c. At meal-times always go to the phone with your mouth full. It is more convincing. If your man hasn't a microphone manner like Stuart Hibberd it is better to answer the call yourself; better for the practice, I mean. Always gain the upper hand by asking more questions than the caller. This is more soothing for you both and transfers some of the responsibility to the caller. Get the facts. Truth is stranger than fiction and safer than friction. If caught cooking, turn off all gas and electricity before answering the call; an extra call after dinner is better than a burnt offering for a meal. If you hear nothing on lifting the receiver, shout loudly "Press button A!" Your voice must carry over the traffic. Then listen carefully. Country people do not willingly waste tuppence to tamper with infernal machines. Sweetening is vital when dealing with supervisors, but the men on at night are usually dears. When it's woman to woman you will know how to cope, sister. You will soon find that one of the most infuriating questions is "When will the doctor be here?" The correct answer is only learnt after hours of practice understudying B.B.C. actors. The answer comes with a light, broken laugh mixed in with this phrase: "Well—sometime——I hope."

How to deal with what you know to be an unwanted call: *You,* "I'm sorry, he's out." *Caller,* "When'll he be in?" *You,* "I don't know." *Caller,* "Can you . . . ?" *You,* "I'm going out." *Caller,* "I really wanted to speak to him personally. It's er . . ." *You,* "Can I take a message?" *Caller,* "Well, not really . . . I . . ." *You,* "Then will you ring at midnight? He'll be in then. There's a baby on the way." (There is one born every minute.) *Caller,* "I see, well, er . . ." *You,* "The milk's boiling over. Goodbye." A final word: don't use the blockage gambits such as "The doctor is just (having a bath, in a snowdrift, the lavatory, the chemist's, town, &c., &c.)." They won't work and he'll never remember the alibi anyway.

My finest hour was when the firstborn of the night supervisor at the local exchange was being delivered. Tied to his post of duty, he rang me up every so often to find out if the doctor was back, saying, "It's so nice to have someone to talk to at a time like this. . . ."

* * *

Our penchant for collecting lamps, antique and otherwise, from the ships in which we serve, ensured that we had two lamps in commission in our temporary house when the "Save-the-Transformers" cut followed close on the "Forbidden Period." A fine swinging model in our country kitchen suggested the roll of the ship and the creak of the timbers, and a table-lamp transformed the dining-room to a Nelson cabin. The problem was candles for stairways and bedrooms. The graceful Nell Gwynns, like the dressing-table candlesticks, were still not unpacked; but we had been using Gurr's embedding paraffin wax (remaining from my pre-war laboratory) to coax morning fires, so at least we had the raw material, and the wax melted quickly in a jam-jar on the hearth. Two tumblers in a basin of cold water, with a string wick hanging centrally from covering pieces of cardboard, were the first moulds. The next refinement was a wick of cut taper, inserted during cooling *au moment critique*; but a corkscrew wick was the reward of the tiro. The result at the end of an hour was: candles, 3; tumblers, 1. The final products had but a faint resemblance to the ecclesiastical species.

Did you know that there is a subtle relationship between the number of wick fibres and the diameter of the periparaffinium? This proportion was not quite right in my giant night-lights—so to the manufactory once more, this time to attempt a carriage-candle. I can now produce a carriage-candle such as they turn out tailor-made from a mould. I use a quarto sheet of paper, rolled to a tube and closed at one end, filled with melted wax and then cooled in water in a quart milk-bottle, and William Tell has nothing on my central placing of the taper. I might even consider accepting honorary membership of the candlemakers' union.

Letters to the Editor

THE INTRAVENOUS DRIP

SIR,—There is a present tendency to regard an intravenous drip—whether of saline, plasma, or blood—as a necessary concomitant to any major surgical procedure.

No-one with experience of what blood-transfusion has contributed to the surgery of injury will question its value. No-one with wide experience of abdominal surgery can deny the extreme importance of intravenous fluids in certain conditions. It is the abuse of the method that I would be glad to see restrained.

It is an abuse to set up an intravenous saline drip as a routine for a major surgical operation, not because the fluid is needed but in anticipation of trouble. An intravenous drip has obvious dangers. It may cause thrombosis, and in the debilitated it increases the likelihood of bronchopneumonia. Because, for instance, once in a hundred times a surgeon may have difficulty with the left gastric artery, must *a hundred patients for gastrectomy* suffer the liabilities of an intravenous drip? If the patient is well prepared for operation and the operative technique is impeccable, most cases of gastrectomy recover with uniform smoothness. A drip is rarely needed. The blunderbuss use of intravenous *fluid therapy* does not improve the results, and does cause trouble.

Other and more able writers have written to the same effect in the last few years; yet, returning to abdominal surgery after some years away, I find myself encompassed by this barrage of bottles, this dangle of drips. The intravenous drip is an exact method of treatment, with precise indications for its use. We need to teach our registrars and house-surgeons what these indications are. We should, I think, make it equally clear that an intravenous drip will not assist a failing myocardium, or take the place of fluids given by mouth into an alimentary canal capable of absorbing them, or compensate for defects in surgical and anæsthetic technique. Such uncontrolled use increases the liabilities of the method.

I trust that this attitude will not be looked upon as reactionary. It is an old adage that there is reason in all things. F. H. BENTLEY.

Department of Surgery, Newcastle-upon-Tyne.

DEATH FROM X-RAY APPARATUS

SIR,—One hesitates to stimulate public alarm by further comment in the case of the radiographer who lost his life in the performance of his duties at the Derby Borough Health Department's chest centre last November (*Lancet*, Jan. 25, p. 156). But I fully endorse the coroner's reported observations to the effect that the corporation had failed in its duty to staff and public in permitting the use of obsolete non-shock-free X-ray apparatus. It is nonsense to say that shock-free equipment is very difficult to obtain.

During the past 16 years, as consultant technical adviser to the Central Bureau of Hospital Information (British Hospitals Association), I have had ample opportunity to observe the reactions of local hospital committees to the suggestion that apparatus which still appears to function adequately should be scrapped. I have found that the situation is governed, not by recommendations from official bodies, consultants, or engineers, but by financial considerations. A qualified radiographer would be upheld in refusing to use unsafe equipment, but familiarity and reluctance to quarrel with the employing authority would make his refusal less likely.

Advice on the subject has always been available through the British Hospitals Association; but, unless there is another accident, nothing short of a general census and survey throughout the country will bring to light the highly dangerous working conditions you describe.

The radiologist is a medical man whose time is fully occupied in the diagnosis and the treatment of medical and surgical conditions revealed within this scientific branch of medicine, and the number of radiologists is greatly exceeded by the number of X-ray sets in existence. In the National Health Service experienced X-ray engineers at regional level, working in consultation with area radiologists responsible to a senior consultant at the Ministry of Health, might be the solution.

Any person can purchase and operate X-ray apparatus, obsolete or new. Legislation is obviously required within the new health services if patient and operator are to be protected against repetition of the distressing occurrence at Derby.

London, S.W.1. H. T. FERRIER.

AMPHETAMINE IN SURGERY

SIR,—Since reading Dr. Houghton's article of Dec. 14 on the effect of amphetamine in pulmonary tuberculosis I have had an opportunity of putting this drug into use.

Six weeks ago a man, aged 54, suffering from chronic suppurative pneumonitis of the right lung which was breaking down into two abscesses and producing about 15 oz. of fœtid sputum a day, was operated upon more or less as an emergency, owing to increasing toxæmia and hæmoptysis. His general condition was poor and the disease was spreading rapidly. Right pneumonectomy was performed and the patient, profoundly toxic, took two days to regain consciousness. When he woke he was extremely depressed and exhausted and had lost any hope of recovering. When, twenty-four hours later, he began to receive two tablets of 'Benzedrine' twice a day his spirits rose quickly. He suddenly started coöperating in the postoperative treatment and, though still extremely weak, responded to the efforts of the physiotherapist to make him cough, move about, and believe in his recovery. He has since completely recovered.

Patients occasionally die, when seriously ill, from resignation and loss of hope. I am convinced that the raising of his spirits by amphetamine was the main factor in his survival.

Hillingdon County Hospital,
Uxbridge, Middlesex. L. FATTI.

TREATMENT OF TUBERCULOSIS

SIR,—The *well-run modern sanatorium* is completely successful within its limits; these are at both ends of residential treatment and are defined without its opinion or consent. The medical superintendent does not choose to admit 80% of his patients in stages II and III; nor does he have any power to implement his advice to them on discharge. He knows quite well that 60% of the B II and 90% of the B III cases will be dead in five years if all he can do for them is to increase their resistance by graduated rest in hygienic conditions; he knows also that his patients can maintain that resistance only as long as they enjoy the sheltered conditions demanded by their lessened function. It is not his fault that sanatorium treatment is "all middle and no ends."

It is twenty-eight years since Bardswell demonstrated that mortality after sanatorium treatment is dependent upon the extent of disease on admission. Every survey since his report has supported him, and several have added to our knowledge the fact that the average length of life from the first appearance of tuberculous cavitation is five years. One conclusion he drew was that something more than passive residential treatment was necessary.

At the admission end we are now trying to find our patients *at an earlier stage of disease* and *at a time* before their resistance is broken. One method is mass miniature radiography. By this method we also help to disclose unsuspected sources of massive infection that are producing adolescent primary phthisis and post-primary adult-type phthisis in children; *for these* sources of massive infection will operate *with or without* the conditions of overcrowding and bad hygiene which prevail amongst large sections of our community.

In the middle we have added collapse therapy. Since its introduction the prognosis of patients at Midhurst Sanatorium in stage B I has improved steadily; for those admitted in the years 1933–35 the five-year survival-rate was 93%. In spite of this everyone will agree that a surgical unit which brings only mental anguish is better shut down. An operation that has not been explained to the patient in its function, preparation, and aftercare as only a modification of the basic principles of rest, and has not the full coöperation of the patient is as useless to him as it is to his physician and surgeon. In 1946 175 major operations were performed in the surgical unit at Papworth ; the only tension observed was in the overworked nursing staff who carried on with magnificent spirit in spite of their depleted numbers since the withdrawal of the Essential Works Order. Many of them have known the benefits of collapse therapy in pneumothorax and thoracoplasty.

At the end of discharge the average patient has a bleak outlook. To maintain his resistance he needs economic security for the leisure outlined for him by the sanatorium superintendent. Any treatment that is not followed by a full pay-packet so that the patient can get sufficient food is a mere mockery. Lessened function and ostracism soon undo the benefits of the sanatorium. We are all anxious to see the rules of health carried out in airy homes and workshops, a high standard of living with the maintenance of real wages, and a happy atmosphere of work. These are the conditions which could rapidly reduce the incidence of phthisis. That we cannot see them in our day is no reason why we should not do more now to provide them for our ex-patients in new village settlements.

Let us keep our sense of balance. Why blame the sanatorium?

R. R. TRAIL
Medical Director, Papworth and Enham-Alamein Village Settlements.
London, S.W.1.

FŒTAL DEATH AND ECLAMPSIA

SIR,—Dr. Zondek in his article of Feb. 1 clarifies some anomalies when he says: "Death of the fœtus may be either primary—i.e., independent of the placenta—or secondary, due to death of the placenta."

Browne[1] states in connexion with eclampsia: "If fœtal death occurs the patient always improves." The following case-history provides an exception:

A woman, aged 42, was admitted in the 26th week of her second pregnancy, after having had an eclamptic fit. Fœtal movements had suddenly stopped 4 days previously; and all signs and symptoms of toxæmia had developed thereafter. She had massive generalised œdema, severe headaches, and epigastric pain on the day of admission. There is no doubt that the fœtus had died as long as 4 days before admission, for it was in an advanced state of maceration when delivered.

In this case it seems that fœtal death occurred independently of the placenta, which when delivered showed only small areas of old infarction.

It appears to be generally accepted that viable placental tissue must be present for pre-eclamptic toxæmia to develop. It is therefore important to realise that the placenta may survive after fœtal death and that, as in the above case, pre-eclamptic toxæmia and eclampsia do not subside, and may even develop. One must guard against complacency when fœtal death has occurred in a case of pre-eclamptic toxæmia or eclampsia.

General Hospital, Nuneaton.
W. P. HIRSCH.

DOCTORS' SALARIES

SIR,—The advertisements in your columns of vacant medical appointments leave me anxious about the sufficiency of salaries offered to medical men for responsible posts, especially for those requiring residence in or about London.

Many salaries are in the region of £800–£1000 a year. I wonder if it is generally realised that it is extremely difficult for a man and his wife, even without children, to live in London on such amounts. The following is the approximate position:

	£
Rent, rates, and garage	200– 250
Food and laundry	208– 260
Electricity, gas, light, coal	25– 35
Holidays and fares	35– 50
Clothes and furniture renewals	100– 150
Insurance, sickness, &c.	50– 100
Telephone	10– 20
Presents and entertainment	10– 25
Car	50– 100
Income-tax	175– 300
	£863–1290

To this must be added the cost of recreation and sport, fees and clothing for children (if any), domestic help, subscriptions to medical societies, doctor's and dentist's accounts, and out-of-pocket petty cash.

Many of today's salaries are instituted on the advice of senior medical men; and what we offer ourselves is the "yardstick" which the Ministry of Health and Treasury officers will use in determining salaries to be paid to doctors by the State.

London, W.1.
HAROLD DODD.

PENICILLIN IN GENERAL PRACTICE

SIR,—In general practice I have found that moderately and very ill patients can often be treated satisfactorily with penicillin by the following method. For a moderately ill patient suffering from a complaint considered clinically suitable for penicillin therapy 100,000 units in distilled water, together with 300,000 units in oil, are given intramuscularly at the earliest opportunity. Daily injections of 300,000 units in oil are repeated thereafter until the patient is out of danger.

The initial dose of penicillin in distilled water seems to produce a rapid rise of penicillin-level in the blood which is lethal to sensitive organisms; meantime the slowly absorbed penicillin in oil gradually takes over and when repeated daily provides an effective and fairly constant level. Ambulatory patients can be given penicillin in oil into the upper arm for several days. The application of cold compresses and immobilisation of the injected arm might be worth trying as an aid to slow absorption.

Louth, Lincs.
ANDREW S. HUNTER.

⁂ The method suggested has considerable advantages, but a daily dosage of 300,000 units will not ensure blood-levels high enough to deal with all strains of staphylococci. The dosage required depends not so much on the severity of the illness as on the resistance of the organism and how well it is entrenched in avascular or necrotic tissue. Thus impetigo may require a higher dosage than cavernous sinus thrombosis. If necessary 600,000 units in beeswax-oil can be given at a dose without causing overmuch local swelling, and this dose can be continued daily for at least 8 days. It should however be noted that beeswax and peanut-oil mixtures are more liable than aqueous solutions to produce hypersensitive reactions.—ED. L.

TOXICITY OF THIAMINE

SIR,—Your timely annotation of Feb. 8 is, I think, the only contribution to this question published in England, apart from my own paper[1] in 1943. I would therefore like to make some comments.

You say, Sir, that Jolliffe[2] did not observe any toxic effects in over 3000 patients and that Borsook administered 100 mg. of thiamine daily to 70 patients intravenously for three years without untoward reactions. All Jolliffe's patients, however, and very probably Borsook's patients, had clinically manifest deficiency disease, but most of the published cases of untoward manifestations after vitamin-B administration did not have manifest symptoms of deficiency at the time of the incident. Moreover, some of these patients had frequent and regular injections of thiamine without any side-effects for a long time, and unpleasant reactions occurred only when the course was interrupted or the interval between injections was prolonged sufficiently to produce hypersensitivity. There is certainly need for further investigation into the frequency and severity of these reactions, especially into the immunological response in the hypersensitive state, and, as you suggest, into the stability of commercial thiamine preparations. This is the more important because the scope for thiamine therapy appears to be widening rapidly—e.g., in Russia large-scale investigations have recently been made of its use for the acceleration of labour and reduction of pain during parturition.

It is likely that most cases with an allergic reaction would have been found to have a well-marked eosinophilia after thiamine administration, as in my case 1.

Your annotation attributes to me the suggestion that the thyrotoxic reaction observed in some cases after thiamine therapy is due to overdosage, and you say: "overdosage in therapy is so common that it must be supposed that supersaturation, with or without faulty excretion, causes the thyrotoxic symptoms and not simply an overdose." The word overdosage was used by me in a quite different sense, and I certainly did not state that the thyrotoxic reaction was due to thiamine overdosage. Furthermore, it is questionable whether simple supersaturation could cause it, since the storage of thiamine in thyrotoxicosis seems to be reduced,[3] and the excretion of thiamine in sweat is more or less proportionally increased with the increased perspiration of the thyrotoxic patient.[4] It is evident that the thyrotoxic reaction in the cases observed was due to the administration of thiamine, but it appears to be caused neither by simple overdosage nor by supersaturation with thiamine. Recent work on the inter-relationship between the various members of the vitamin-B group [5] suggests that disturbance of the balance between the members of the vitamin-B group after administration of comparatively large doses of thiamine may precipitate the thyrotoxic symptoms.

[2] Jolliffe, N. *J. Amer. med. Ass.* 1941, 117, 1496.

Lastly, you say in your annotation that "the anaphylactic phenomena have been shown to be due to thiamine and not to the usual preservative chlorobutanol" and quote Mills [6] and Haley and Flesher.[7] But the latter carried out a series of experiments on rabbits and concluded that "anaphylaxis plays no part in thiamine hydrochloride toxicity as seen in rabbits. However, injections of a sensitising dose apparently increase the resistance of the animal to toxic injections of thiamine hydrochloride."

London, W.1. Z. A. LEITNER.

LUCKY LUTON

SIR,—Your annotation on Some Luton Families should lead many of us to read Mr. C. G. Tomlinson's book *Families in Trouble.* Luton is so fortunate in its social and economic structure that its "submerged tenth" is reduced to a submerged hundredth. In such happy circumstances the submerged family stands out in striking contrast with its social surroundings and is all the more easily studied.

Amongst the factors causing submergence the first mentioned is "subnormal mental capacity"—a finding with which all who have studied this problem will agree. Your annotation then proceeds: "Moreover, most of the families exhibiting mental deficiency are not problem families; so that to be subnormal mentally is by no means a necessary first step towards becoming a social problem." How can these statements be reconciled?

R. P. GARROW
Hornsey, London, N.8. Medical Officer of Health

*** We intended to suggest that mental subnormality in a family does not necessarily mean that it will become a social problem.—ED. L.

PSYCHOSOMATIC APPROACH TO ORTHOPÆDIC SURGERY

SIR,—Mr. Le Vay in his enlightened essay (Jan. 25) emphasises the relation between the emotional state and recovery in orthopædic conditions. He pays a graceful tribute to the orthopædic service of the Royal Air Force; but he makes a statement that might be misunderstood. He says: "The magnificent results in the Royal Air Force were achieved with such first-class material that it was possible to separate the sheep from the goats without being wasteful, and for a specific end." Royal Air Force orthopædic rehabilitation centres catered not only for aircrew but for ordinary ground tradesmen who represented a normal cross-section of labour available for industry. The final results after rehabilitation in the two groups—aircrew and ground personnel—were comparable.

Orthopædic rehabilitation was organised on an injury-group basis. The personalities of men undergoing rehabilitation were, as the result of six years' experience, classified as follows: (1) first-class personnel who would get better by their own efforts; (2) the average type who could be greatly improved by the organisation; (3) the passive non-coöperators whose morale could be improved by the group they were working in; and (4) the active non-coöperators who were treated as individuals, being removed from their injury group because of their bad influence but still retained at the centre. The only "goats" not retained and treated by the organisation were the basically abnormal or psychotic personalities. We confirmed that every case of physical trauma has some psychological trauma whose degree is conditioned by the basic personality.

The problem of returning aircrew to the air was similar to that of returning the miner to the pit: both go back to the environment which gave them their injury. Sir Reginald Watson-Jones has organised rehabilitation centres for miners in England, Scotland, and Wales, using the proven methods of the Royal Air Force, and these centres have in the past three years had results similar to those at the R.A.F. centres.

R.A.F. MEDICAL OFFICER.

THE FAMILY

SIR,—Prof. J. C. Spence's lecture summarised in your issue of Jan. 11 is another welcome sign of increasing interest in the wider implications of health. If, as would seem probable, the family is the normal environment of the human person, in which, especially during childhood, he can most readily attain wholeness of being, this provides a useful yardstick for assessment of every new or old ideology, law, or fashion. If its effect is to strengthen the family institution, it is good; otherwise it is bad.

The test may be demonstrated in a seemingly small matter in my own sphere of work, public health and school medicine. Midday meals at school for all children: is the principle good or bad? While a convincing case can be made for meals at school for some children in some circumstances, their effect if taken by all children as a normal part of school life would be to loosen home ties and so weaken the family.

By this test a great deal of what has rather uncritically been accepted as evidence of progress is found to be of dubious value. Professor Spence has condemned the industrial revolution for its effect upon neighbourliness. (It stands equally condemned for destruction of joy in craftsmanship, for the divorce from the land, and for mechanical, passive means of recreation.) The lapsing of the mass of the population from positive religious belief might be shown, I believe, to have been equally disastrous for human wholeness and happiness. And while he would be bold who, in England today, assailed the notions of equality and liberty, to which we all pay lip-service, it may be well to consider carefully what we mean by these terms, how far we are in fact equal or free, and how much good the current conceptions are to us.

To come from theory to practical suggestion. While we continually talk about the importance of the family, there is scope for study of the family in fact. Some excellent work has, of course, been done in this respect by the workers at the Peckham Health Centre, and contributions are made from time to time to the medical press by medical officers of health and others on particular family problems and on problem families. But the field still awaits exploration, and for those whose whole-time duty it is to study and advance the public health it seems as important as ever was epidemiology in a past generation.

B.A.O.R. J. V. WALKER.

RUBELLA AND CONGENITAL DEFECTS

SIR,—I have heard of two recent cases of rubella early in pregnancy. In one case the mother had rubella in the first 3 weeks of pregnancy. It was a mild attack with no sore throat or enlarged glands, and she was in bed for only 2 days with slight fever and a rash. The child, born in 1946, has bilateral cataract and is also deaf. In the second case the mother had a similar attack of rubella at 8–11 weeks of pregnancy. The risk of congenital defects was recognised in this case because the mother had heard Professor Haldane's reference to it on the wireless, so the child has been carefully observed. The child is now 3 months old, and no defects have appeared. There is certainly no cataract or heart lesion, and no severe deafness; it is of course too early to say that hearing is normal.

It seems particularly important in the present state of our knowledge that cases should be recorded where the mother has rubella early in pregnancy and the child is born without any malformations.

Galton Laboratory, University College, London. JULIA BELL.

AMYLOID MACROGLOSSIA

SIR,—Dr. M. D. Baber's case (Feb. 8) is of great interest and helps to show that cases of primary amyloidosis, notably those accompanied by obvious macroglossia (the Lubarsch-Pick syndrome), are not of such extreme rarity as was supposed until ten years ago.

When an example was described by Weber, Cade, Stott, and Pulvertaft in 1937[1] macroglossia due to amyloidosis was unknown in Britain, though cases had been published in America. Since then besides the two recorded by Barnard, Smith, and Woodhouse[2] quite a number of cases of primary amyloidosis—with or without macroglossia—have been brought forward and others have remained unpublished. Personally I have seen two typical examples of the Lubarsch-Pick syndrome shortly before the commencement of the war, and I hope they will be described by the doctors through whose kindness I was able to examine them. I suspect that some cases recorded in medical literature—even during the last ten years—have not been recognised as examples of the Lubarsch-Pick syndrome.

For instance, I recently came across the account of a case demonstrated by Dr. G. H. Belote[3] as one of "tertiary syphilis with amyloid deposits in the eyelids, lips, tongue, pharynx and larynx" in a man, aged 56, complaining of sore tongue. Ten years previously the tongue had shown "some thickening, but no ulceration." When this case was demonstrated there were waxy flesh-coloured papules on eyelids and lips; and there was thickening of the tongue, of the alveolar regions, of the tonsillar region, of the pharynx, and of the larynx. The serological reaction for syphilis was negative, and a biopsy showed amyloid material.

Surely, that was an example of the Lubarsch-Pick syndrome. I do not know if it was described later at greater length.

London, W.1. F. PARKES WEBER.

SIR,—Dr. Margaret Baber's report of another case of amyloid macroglossia (Feb. 8) prompts a brief note of two further cases of atypical amyloidosis, both men, one with macroglossia.

CASE 1.—A man, aged 59, bedridden for two years, died at home in October, 1945, in a manner suggesting congestive heart-failure. He came to necropsy because he had received a full military pension for rheumatoid arthritis since the war of 1914–18. The notes are summarised: widespread rheumatoid deformities of all limb joints; wasting; gross generalised œdema; pallor and puffiness of the face, with thick lips; tongue enlarged to fill the mouth; sterile pus in one knee-joint; heart 420 g.; microscopically, much amyloid in the tongue, heart, kidneys, spleen, and adrenal glands. (One of the cases reported by Edwards[4] had rheumatoid arthritis.)

CASE 2.—A boiler fireman, aged 61, was admitted to hospital in August, 1945, with congestive heart-failure after 18 months of ill health; he had dyspnœa, retrosternal pain on exertion, aching legs on exertion, giddiness, insomnia, and swollen ankles. The blood-pressure was 60/35 mm. Hg in hospital, and the hæmoglobin 77%. The condition was diagnosed as myocardial fibrosis. Necropsy four hours after death on the third day in hospital showed œdema of legs, moderate ascites, and bilateral hydrothorax; large thick-walled heart (580 g.), pale, of rubbery consistence, and with many subepicardial petechiæ; spleen (340 g.) of a striking red colour, firm and friable, resembling a cake of wax; no macroglossia. Microscopically, amyloid was present in very large amount in heart, spleen, kidneys, and adrenals; in rather less amount in liver, pharynx, tongue, gastrocnemius, pancreas, meninges, a meningioma, diaphragm, prostate, thyroid, and lung; and none was found in biceps and skin. The spleen contained many giant-cells of foreign-body type, presumably a reaction to amyloid which almost replaced the whole bulk of the organ. The gastrocnemius also showed a striking myositis. (The notes of more than one case previously recorded mention pains in the legs comparable with claudication.)

Specimens and sections of these two cases were demonstrated at a meeting of the Association of Clinical Pathologists in January, 1946.

Where the amyloid deposit is slight, it is in sheaths of smaller blood-vessels and in interstitial fasciæ. The three cases which have now been seen in this department suggest that atypical systemic amyloidosis is a disease sui generis, which may affect any tissue in the body.

Department of Pathology, Royal Infirmary, Preston. F. B. SMITH R. T. COOKE.

PREVENTION OF EPIDEMIC NEONATAL DIARRHŒA

SIR,—In his article of Jan. 11 Mr. Stern suggests that "infection may be spread by the heavy and increasing contamination of the film which forms in feeding-bottles in constant use." Is it not time that the narrow-necked bottle was discarded altogether and the 'Hygeia' type of wide-necked, straight-sided bottle, with large rubber teat, substituted? I believe these bottles are widely used in Canada and the U.S.A., and feel sure they could be produced in England too. The hygeia bottle is readily cleaned with hot water, to which washing soda has been added, and a stiff brush; and all parts of the bottle are easily accessible to the brush, which is patently not so with the narrow-necked bottle. The formation of film is thus easily prevented, and the bottles must of course be boiled for each feed.

With regard to the suggestion that sterilisation by boiling destroys rubber teats, I have been using the same teat for my own baby for over 4 months now. It has been boiled daily for at least 5 minutes and shows no sign of perishing yet; and this is not an isolated experience.

Johannesburg, South Africa. ELIZABETH LUND.

RECRUITMENT OF STUDENT NURSES

SIR,—Speaking from personal experience, based on the entry of a daughter into general nursing training, I strongly support the need for revision of the pay of student nurses along the lines suggested by your correspondent of Feb. 8. The position is worsened by the fact that the Commissioners of Inland Revenue have decided that no allowance is given for any child who earns more than £50 per annum (except for scholarships). This decision at once excludes any tax relief for parents paying higher rates of tax who have been public-spirited enough either to agree to, or to stimulate, the entry of their daughters into nursing.

It is obvious, of course, that if the pay of student nurses is increased similar increases must be granted to all the more senior grades. Increases beyond those proposed in the Rushcliffe scales are needed, in my opinion, if conditions in the nursing profession are to compete with those of industry and commerce.

Public Health Department, Walthamstow. A. T. W. POWELL.

THYROID AND COLD SENSITIVITY

SIR,—Dr. S. L. Simpson makes the interesting suggestion (March 8) that thyroid should be given to healthy volunteers in order to investigate its capacity to increase resistance to cold and induce well-being. A word of warning is needed, however, should such an experiment be undertaken.

S. W. Patterson[1] has warned that thyroid may cause addiction. It acts as a tonic by increasing energy, improving the appetite, and enhancing mental alertness; and neurotics are apt to take to it. The widespread administration of thyroid to otherwise healthy obese patients and to those with assumed "slight glandular underfunction" has created quite a few cases of moderate addiction. Happily, the metabolic effects are often not too harmful, possibly because the present diet is poor in simply an overdose." The word overdosage was used by me in a quite different sense, and I certainly did not state that the thyrotoxic reaction was due to thiamine overdosage. Furthermore, it is questionable whether simple supersaturation could cause it, since the storage of thiamine in thyrotoxicosis seems to be reduced,[3] and the excretion of thiamine in sweat is more or less proportionally increased with the increased perspiration of the thyrotoxic patient.[4] It is evident that the thyrotoxic reaction in the cases observed was due to the administration of thiamine, but it appears to be caused neither by simple overdosage nor by supersaturation with thiamine. Recent work on the inter-relationship between the various members of the vitamin-B group [5] suggests that disturbance of the balance between the members of the vitamin-B group after administration of comparatively large doses of thiamine may precipitate the thyrotoxic symptoms.

Lastly, you say in your annotation that "the anaphylactic phenomena have been shown to be due to thiamine and not to the usual preservative chlorobutanol" and quote Mills [6] and Haley and Flesher.[7] But the latter carried out a series of experiments on rabbits and concluded that "anaphylaxis plays no part in thiamine hydrochloride toxicity as seen in rabbits. However, injections of a sensitising dose apparently increase the resistance of the animal to toxic injections of thiamine hydrochloride."

proteins, and perhaps also because of the formation of antihormones. I saw such a patient quite recently who had taken 15 grains of thyroid daily for eighteen months and had remained well, except for a tachycardia of 106–120. It took more than six months to reduce the dose to 1½–2 grains daily.

London, S.W.3. V. C. MEDVEI.

STAMMERING

SIR,—Speech therapists should be indebted to Dr. Chrysanthis (Feb. 15) for his data on the incidence of stammering in the Greek elementary schools of Nicosia, Cyprus. A number of factors mentioned in this connexion—such as anthropological peculiarities, intelligence, handedness, and sex—are still so controversial that they cannot be discussed briefly. I must, however, challenge the statement that "according to many investigators, stammering is unknown among the Chinese, whose language consists of monosyllables."

This opinion can be traced back to Colombat d'Isères (*Traité de tous les vices de la parole et en particulier du Begaiement*, Paris, 1840). He mentions that a boy born of a Chinese mother and a French father was able to speak Chinese perfectly but stammered when speaking French. With reference to Colombat's opinion, James Hunt, in his book on stammering (London, 1865), explicitly says that "the assertion which has been made on various occasions, on very slender grounds, that there are no stutterers in China is refuted by the fact that the Chinese language possesses a term for impediments of speech." Kussmaul (*Pathologie der Sprache*, 1877) again gives it out to be an established fact that there are no stammerers in China. He attributes stammering to a lesion of a hypothetical centre of syllable coördination, and it is therefore probable that he adduced Colombat's statement concerning the absence of stammering in people speaking a monosyllabic language in support of his theory. Kussmaul was a great expert on the pathology of speech, and it is therefore not surprising that, on his authority, other authors took the statement for granted. Chinese physicians whom Gutzmann (*Sprachheilkunde*, 1912) asked about the truth of Colombat's statement were greatly astonished and declared that stammering was just as common in China as in Europe. They also informed him that the Chinese term was *kchi-ko*.

For the sake of historical accuracy I should be grateful if you would publish these lines, particularly as the erroneous statement has since then been quoted in the daily press.

Tavistock Clinic, London, W.1. LEOPOLD STEIN.

BENIGN LYMPHOCYTIC MENINGITIS AND GLANDULAR FEVER

SIR,—I was interested in Sir Henry Tidy's article of Dec. 7, particularly because by chance I recently discovered another study of this relationship from America. Coogan and colleagues[1] concluded that "a suggestion is contained here that at least some cases of lymphocytic meningitis are really cases of infectious mononucleosis with meningismus." They quote Huber,[2] who reported 3 cases of glandular fever exhibiting meningismus, 2 of which showed a lymphocytosis in the spinal fluid.

C.R.S., Brancepeth, Co. Durham. R. N. JOHNSTON.

TRAUMATIC PARAPLEGIA

SIR,—In your account of the recent discussion on traumatic paraplegia at the Royal Society of Medicine (Jan. 4, p. 23) you misquote my instructions for the introduction *of a suprapubic catheter. It should be* inserted at the highest point of bladder dullness, or midway between the umbilicus and the symphysis—whichever is the *lower*. There is no advantage, and some possible danger, in a tube put in higher than the midpoint.

Your leading article of Feb. 15 (p. 258) seems to infer that I advocate permanent suprapubic drainage for these cases. This is far from being the case, and I have pointed out that one of the advantages of the small high suprapubic fistula is the readiness with which it closes when the tube is removed. The majority of our cases at Stoke Mandeville have their bladders closed, and much of my time there is spent in closing surgically the bladders of those who have been unfortunate enough to be given a low fistula. The use of the suprapubic catheter is to provide adequate drainage during the period before the development of automatic bladder activity or the return of voluntary micturition, while at the same time preventing serious or ascending infection. In my experience it does this more safely and certainly than the urethral catheter, even with tidal drainage.

London, W.1. E. W. *RICHES.*

THE PERIODICALS

SIR,—The suspension of the periodicals, and the manner in which it was effected, raise considerations whose importance has not, I submit, been fully appreciated. Two explanations of the suspension, conflicting with one another and with the facts, were given in the two Houses of Parliament, but in both Houses all pretence of any statutory sanction was immediately abandoned. On Feb. 25 in the Commons, the Prime Minister, challenged at question time for the statutory authority upon which suspension had been made, declared, twice over, that it was "done by agreement" between the Periodical Proprietors Association (P.P.A.) and the Government. Lord Chorley, replying for the Government in the Lords (Feb. 27), repudiated the "agreement" argument. "Suspension of publication was secured," he said, "by an instruction issued after consultation with bodies representing major interests in the newspaper and periodical press." Speaking with all the authority of a professor of law in the University of London, he declared categorically that "instruction is the word which I think most accurately describes" the procedure adopted. The ascertained facts are that Mr. Shinwell had issued the "instruction" *three days before any consultation with the P.P.A. was attempted.* The "instruction" had, and was intended to have, all the appearance of an imperial rescript. The P.P.A. taking that view of it, and confronted with an accomplished fact, had no alternative but to "agree."

House of Commons. E. GRAHAM-LITTLE.

⁂ Like the *Economist*, we felt that "some latitude of authority should be conceded to His Majesty's Government, if they are acting in good faith in an undoubted national emergency," but we trust that "instructions" of this kind will never be issued again. The P.P.A. agreed with the Ministry that, in order to equalise sacrifices, duplicated issues should not be published; and our membership of the P.P.A. therefore prevented production of the token issues by which we had hoped to maintain continuity of publication.—ED. L.

WELFARE OF DEAF CHILDREN

SIR,—My attention has been drawn to the letter of Miss Edwardes, secretary of the Deaf Children's Society, in your issue of Dec. 21 (p. 923). There is much to be commended in this letter but it raises some points which call for a reply.

Deaf children have suffered too long from lack of proper facilities and from the fact that their parents have been given incomplete or inaccurate advice. There is not sufficient accommodation at the moment for all deaf children to be admitted to schools immediately their affliction is diagnosed, but it is essential that practitioners, and the parents of deaf children, should be made aware of the best and only satisfactory method of providing for their education.

Your correspondent says that the young deaf child need not be instructed by a fully qualified teacher. But the whole foundation of the deaf child's education and his whole outlook on life depend on the training in his early years. Only the qualified teacher can meet the needs of the young deaf child. It is to be hoped that the efforts of parents and such societies as that represented by your correspondent will be directed to ensuring increased facilities for young deaf children under fully qualified teachers.

A further point is the advisability of young deaf children attending a residential school. There are comparatively few deaf children whose homes are so situated that it is convenient or suitable for them to attend day schools even when they have reached normal school age let alone nursery-school age. Even in the large cities the travelling involved would often be much more than a young child could be expected to undertake, and

---

1. Coogan, T. J., Martinson, D. L., Mathews, W. H. *Illinois med. J.* 1945, 87, 296.
2. Huber, W. *Schweiz. med. Wschr.* 1938, 68, 892.

it would probably be out of the question for the mother to escort her child a long distance twice daily. It must be our purpose to ensure that special education is provided for *every* deaf child at the earliest possible age. Only residential schools can meet this need. The system will not fulfil the requirements of the Education Act if it caters only for the few who can attend day schools. The underlying principle of all residential schools for young deaf children is to approximate as nearly as possible to home conditions, with a staff of people specially qualified to care for, and deeply interested in, the welfare of the young deaf child.

A. W. KETTLEWELL
Royal School for the Deaf, Exeter. Hon. Secretary.

EMPLOYMENT OF EPILEPTICS

SIR,—Many of your readers are interested in one aspect or another of the difficult problem of the epileptic. These unfortunate people often find it hard to secure a place in industry even with the assistance of the D.R.O.'s at the employment exchanges. A considerable number are known to be drifting about in the community in need of medical advice or of help with their social problems.

In an endeavour to meet this situation a clinic has been established by the London County Council at St. John's Hospital, St. John's Hill, Battersea, on Wednesday afternoons, at 2.30. The medical officer in charge is a senior officer seconded from St. Ebba's Hospital, and an experienced psychiatric social worker is in attendance. The clinic works in close association with the employment exchanges and with the colonies for epileptics, and it is understood that excellent results are being obtained. Doctors in private practice or on hospital or clinic staffs who wish for advice on epileptic patients living in London should apply to the psychiatric social worker at the hospital.

ALLEN DALEY
County Hall, London, S.E.1. Medical Officer of Health.

Parliament

ON THE FLOOR OF THE HOUSE

MORE heat in the Commons again last week. Monday's announcement of martial law in Palestine was received grimly. Then there was a flaming row over some Africans convicted of murder on the Gold Coast who were due for execution next day. The royal prerogative, the governor's power to exercise it, and the Colonial Secretary's power to influence the governor got all mixed up, and members raising points of order were sprinkled over the benches like firecrackers. A dubious case was used, very warmly, as a method of attack on a Minister. The House is "hetting up" because opponents of the Government do not like the speed with which they are carrying out their election programme. A long-drawn struggle followed on their decision to fix a definite time-table for the discussion and passage of the Transport Bill and the Town and Country Planning Bill. This time-table was the answer to the Opposition's refusal to come to an arrangement "through the usual channels" which would have enabled business to proceed at a reasonable pace. For it seems probable that now there will be all-out warfare all the time, and that means long sittings—all-night sittings—calling in the forces of physical exhaustion to upset the programme. On Tuesday there was comparative calm, but even then there were some heated exchanges about Polish resettlement, and the Bill was not read a third time and passed until 3 A.M.

On Wednesday the House turned to a two days' debate on India, opened by Sir Stafford Cripps and concluded on Thursday by the Prime Minister in a speech which was probably the best he has made in Parliament and was cheered by his supporters for some two minutes. The Opposition, led by Mr. Churchill, did not dissent from the objective of the Government—the bringing of India to self-government—but objected to their fixing a date next year after which Britain will not continue to carry the responsibility of the administration of India. On the other hand, the Labour view is that the Opposition plan would involve us in another twenty years in India, which is out of the question. India will have the opportunity of either remaining in or going outside the British Commonwealth, but we may hope that in either case our relations with her will be good. Dealing with the criticism that we are not discharging our duties to the minorities, Mr. Attlee described his visit to a village of the scheduled castes in Madras. "There was not even a road that was allowed to be laid in the village." And this was after a hundred years of British rule. The existence and position of the scheduled castes is part of the whole Hindu social system, and we, the British, cannot change the Hindu social system: the responsibility rests on the Indians themselves. Mr. Attlee also said a word on our obligations in India: "of course His Majesty's Government will carry out all their proper obligations to members of the Services, who can be assured that they will not be let down." That statement will take a load off the minds of the Civil Service and the I.M.S.

On Friday the estimates of the Ministry of Food were subjected to a grilling examination but were not fully challenged. Prices are going up; the wholesale prices in the U.S.A. have risen by more than 30%, and that is giving a lead to prices elsewhere. We shall have to produce even more than we have been doing of foods for our own consumption.

MEDICUS, M.P.

QUESTION TIME

Rationed Foods and Nutrition

Mr. W. ELLIOT asked the Minister of Food whether the intake of rationed food of the average British rationed person was at present of the order of 1400 calories per day; and what respective supplement in calories the average person in a household and the single person living alone was reckoned by him to obtain from a normal expenditure of points.—Dr. EDITH SUMMERSKILL replied: The figure of 1400 calories for rationed foods is reached by strict reference to the amount of such foods allowed to the ordinary consumer, whereas the average of 2900 calories covering all commodities is obtained by dividing the calorie value of the total foods moving into civilian consumption by the number of the civilian population. The two cannot therefore be readily compared. The dispersion around the average of 2900 calories must be very wide, as it includes at one end of the scale such consumers as children, whose intake is considerably less than the average, and at the other end heavy workers, who receive considerably more. Between these extremes there are many gradations. The average of 2900 calories over the whole community is greater than the weighted average requirement of the population.

Calorie Value of Meat Rations

Sir GIFFORD FOX asked the Minister of Food if he would state the calorie value of the meat ration issued to civilians, prisoners-of-war, and the Armed Forces, respectively, in this country; and how it compared with this time last year.—Mr. J. STRACHEY replied: The approximate daily calorie value of the meat ration is 160 for civilians, 150 for prisoners-of-war, and 340 for the Armed Forces at the present time. In January, 1946, the figures were about 150, 150, and 380, respectively.

Rations in British Zone

Mr. T. C. SKEFFINGTON-LODGE asked the Chancellor of the Duchy of Lancaster if he would list those foodstuffs in the British zone, the distribution of which had so far fallen below the 1550 calories ration-scale agreed on in the Anglo-U.S. bi-zonal food programme.—Mr. J. HYND replied: In January the only material deficiency was in processed cereal foodstuffs, representing an average loss of about 80 calories a day. In February there were additional shortages of cheese, skimmed milk, and, in Niedersachsen only, of fish; these increased the daily loss to about 100 calories. The deficiency in cereals for both months will be made good as soon as possible; the other items cannot be replaced. Meat was also short in February, although extra distributions of sugar prevented any loss of calories.

Sanatorium Beds

Mr. JOHN MORRISON asked the Minister of Health what was the total number of cases suffering from pulmonary tuberculosis who had applied, or been recommended, for admission to a sanatorium and who had not yet been found accommodation and what steps he proposed taking to expedite this matter.—Mr. JOHN EDWARDS replied: In England and Wales, at Dec. 31, 1946, the number who had been on waiting-lists for institutional treatment for longer than ten days was about 7000. The chief difficulty is shortage of staff, and the utmost efforts are being made to remedy this.

Obituary

MARK BATES

O.B.E., B.M. OXFD, F.R.C.S.

THE death of Mark Bates on Jan. 25 ends 68 years of family service to Worcester and its hospitals. His father, Tom Bates, was appointed surgeon to the Royal Infirmary in 1879, and his brother, another Tom Bates, was still on the staff of the hospital when he died in 1943.

Mark Bates was born at Worcester in 1881 and educated at the Cathedral King's School. With a scholarship he went to St. John's College, Oxford, in 1899, and later to St. Bartholomew's Hospital. After graduating B.M. in 1908 he held house-appointments at St. Bartholomew's Hospital and at the Royal Infirmary, Worcester, before settling in practice in his native town. In 1913 he took his F.R.C.S. and the following year he was appointed anæsthetist to the Royal Infirmary, but almost at once on the outbreak of war he joined the R.A.M.C. and left Worcester to become surgical specialist to no. 15 General Hospital at Alexandria, and later senior medical officer in the Haifa area. Twice mentioned in despatches, he was appointed O.B.E. in 1919. On demobilisation he returned to Worcester and was appointed surgical pathologist to the infirmary and in 1922 full surgeon, an appointment which he held till in 1932 he decided to specialise in venereal diseases and took charge of the clinic at the infirmary.

"Mark Bates was a proud son of Oxford," writes W. H. McM., "and his greatest joy was to revisit the quadrangles and gardens of his undergraduate days; then sauntering out hatless from the Golden Cross he would browse at the bookshops and libraries. Once for a wager he walked from Oxford to Worcester in 24 hours. Setting off up the Woodstock Road soon after noon on a fine day in June with an escort of supporters to encourage him for the first few miles, he reached Chipping Norton in time for an evening meal, had a rest on the top of Bourton Hill, and entered Broadway village at dawn. The sight of the clear water in the village horse-trough tempted him to refresh his weary limbs. Not a soul was abroad, so he undressed and bathed in preparation for the third stage of the 58-mile journey. He reached his father's home in the Foregate Street just as the bells of St. Nicholas Church struck noon.

"Mark and his elder brother Tom, though dissimilar in many ways, both resembled their father in possessing a restful personality, a cultured mind, and a love of tradition. Medical newcomers to Worcester will recall the welcome and hospitality invariably extended within the first week by each of the Bates brothers. Although modest and retiring by nature, Mark could, on occasions, arouse himself to fine oratory, and his recent spirited diatribe against English cooking will long be remembered amongst his fellow members of the Vigornian Clinical Society.

"Clean-shaven, with straight white hair and blue eyes, he was to be seen almost daily, in a camel-hair coat, his hands clasped behind his back, strolling towards the post office, while ruminating on the clues in the *Times* crossword puzzle."

JOHN BROOK HENDERSON HOLROYD

M.R.C.S., D.A.

Dr. John Holroyd, anæsthetist to the Sheffield Royal Infirmary, died on Feb. 8 at the age of 68. After a short period in business he entered the Sheffield medical school in 1905 and qualified in 1910. He held house-appointments at the Royal Hospital, Sheffield, before he went to the Birmingham Midland Eye Hospital as senior house-surgeon. But he decided not to specialise in ophthalmology and he returned to Sheffield to spend a year as a medical officer at the City General Hospital, later settling in practice in the Pitsmoor district of the city. During the 1914–18 war he served in India and elsewhere with the R.A.M.C.

Holroyd had always been attracted to anæsthetics, and early in his career he became one of the visiting anæsthetists to the Royal Hospital in Sheffield and later to the Royal Infirmary. One of the original members of the council of the Society of Anæsthetists, in 1935 he was awarded the diploma in anæsthetics. In 1942 he gave up his general practice to devote himself to his specialty. During the recent war he gave valuable service as an anæsthetist in the E.M.S., and as temporary lecturer in anæsthesia in the university. He insisted that every new resident at the Royal Sheffield Infirmary and Hospital had to give anæsthetics under the supervision of one of the honorary anæsthetists before being allowed to take a case on his own responsibility. For many years he had offered a gold medal to the student who did best in a competitive examination on the theory and practice of anæsthesia, and it is hoped that the faculty of medicine will perpetuate the Holroyd medal in memory of its founder who did much for his students and for anæsthesia.

"With Jack Holroyd in charge of the anæsthetic," writes the surgeon with whom he worked for 25 years, "the surgeon's anxiety on that score was eliminated. He always gave due warning as to what might be attempted with safety and always carried on quietly and efficiently, starting all anti-shock therapy without bothering to wait until it was suggested to him. He took perhaps a long time in the opinion of some in the induction stage, but this is no fault, and when once the patient was under there was never any impatience shown, nothing mattered to him but the well-being of the patient. Our relationship was most happy, for each had the confidence of the other, and the fortunate result from what often appeared to be a desperate surgical interlude was due in no small measure to the skill, care, patience, and personality of the anæsthetist."

FERGUS LESLIE HENDERSON

M.B. GLASG.

Dr. F. L. Henderson, radiologist to the Glasgow public-health department, died on Feb. 28 at the age of 54. A son of the manse, he was educated at Glasgow Academy and in 1914 graduated M.B. at the University of Glasgow. After a short period in general practice and in the city hospitals his interest in radiology was stimulated by the late Dr. James Riddell, one of Glasgow's pioneers in the use of X rays, and with Sir Alexander Macgregor and the late Dr. John Wilson he correlated the appearances which he saw in the film with the findings of the clinician and established the place of the radiogram in diagnosis. When the corporation opened its first radiological diagnostic station at Ruchill, Dr. Henderson was therefore their natural choice as consultant, and as the tuberculosis service expanded he became the final arbiter on the chest radiography carried out by the public-health department. When, in 1923, the McAlpin Home introduced radiological equipment he became consultant there, and this work brought him into intimate contact with a wide circle of medical colleagues, who as the years passed came to value his opinion more and more. He was also radiological consultant in the West of Scotland to the Ministry of Pensions, and for many years he was in charge of radiotherapy in the Cancer Hospital.

Important as his medical work became, two other interests were the crown of his life. A man of sincere religious beliefs, he formed an association with Ruchill Church in 1914 when he became an officer in the 60th company of the Boys' Brigade. Two years later he assumed charge of the company, and during the last thirty years built it up to become one of the largest and most effective in the city. A pioneer in his realisation of the need for proper recreational opportunities among working-class boys, he set in train schemes which led to the purchase for the company of an athletic ground at Maryhill which might have been the envy of any wealthy public school. His constant interest in the lives of members and ex-members made "the Doc," as he was called, a guiding influence for a host of boys in Maryhill, and his holidays were all spent with them at a large camp which he organised at Crianlarich. His other enthusiasm was music, and the 60th's annual Gilbert and Sullivan productions were excellent. A life-long supporter of the Scottish Orchestra, he was a valued member of the committee of management for many years. His circle of close friends was small, for his natural modesty and shyness kept him somewhat aloof, but a wide circle respected him as a man of real integrity whose sense of responsibility was great and whose opinion was always fearless and forthright. W. W. G.

ALFRED CLARK

F.R.C.S.E.

Dr. Alfred Clark died in Auckland, New Zealand, on Feb. 1, as the result of X-ray injuries received some forty years ago. Though his disability was severe—he twice had amputations of his right arm—he faced it with courage, discussed it with detachment, and did not allow it to interfere with the important research in tropical nutrition which he undertook after the 1914–18 war.

Born at Cerne Abbas, he was educated at Dorset County School and at University College, London. He continued his medical studies at the Middlesex Hospital, taking the Scottish Conjoint qualification in 1892. Six years later he obtained the Edinburgh fellowship. After a period of general practice in this country he emigrated to New Zealand, where he worked among the Maoris and served as radiologist to the Auckland Hospital. Later he was appointed school medical officer to that city. During the 1914–18 war he served with the N.Z.M.C. in Egypt, France, and Germany.

In 1928 he began his nutritional work for the Colonial Office in Trinidad, and in 1932 in the *Transactions of the Royal Society of Tropical Medicine and Hygiene* he discussed the relationship of diet to nephritis in the tropics. The following year, for the Medical Research Council, he investigated in Nigeria the syndrome of epithelial and nervous lesions. He observed that cyanogenic foodstuffs, such as maize, millet, and sugar-cane, were common in the diets of all people suffering from pellagra and allied nutritional diseases, which he therefore concluded were due to slow prussic-acid poisoning (*J. trop. Med. Hyg.* 1939). During the late war Dr. Clark continued his nutritional research in Ceylon, though latterly he was much handicapped by ill health.

Births, Marriages, and Deaths

BIRTHS

Arthur.—On March 4, at Northampton, the wife of Dr. W. D. Arthur—a son.

Barendt.—On March 4, the wife of Dr. G. H. Barendt, Southampton—a son.

Down.—On Feb. 21, at Exeter, the wife of Dr. A. H. G. Down—a son.

Gask.—On March 6, at Oxford, the wife of Dr. John Gask—a son.

Grant.—On March 2, at Woolwich, the wife of Dr. W. R. Grant—a son.

Harley.—On March 7, at Reading, the wife of Dr. H. C. Harley—a daughter.

Harper.—On March 1, at Maidstone, the wife of Mr. Ernest Harper, F.R.C.S.—a daughter.

Laing.—On March 3, at Southampton, the wife of Mr. J. E. Laing, F.R.C.S.E.—a daughter.

Newnham.—On Feb. 28, at Beaconsfield, the wife of Dr. Claude Newnham—a son.

O'Sullivan.—On March 5, in Manchester, the wife of Dr. J. G. O'Sullivan—a son.

Warren.—On Feb. 26, in London, the wife of Dr. A. J. Warren—a daughter.

Wylie.—On March 3, at Oxford, the wife of Dr. J. A. H. Wylie—a son.

MARRIAGES

Langford—Potter.—On March 1, at Bramley, Surrey, Richard Crawford Langford, M.R.C.S., lieut.-colonel R.A.M.C., to Lois Potter.

DEATHS

Ballinger.—On March 1, at Malvern, Owen David Ballinger, B.M. Oxfd, aged 48.

Dewar.—On March 5, at Arbroath, William Johnston Dewar, M.D. Aberd.

Frame.—On March 2, at Worthing, David Frame, M.D. Glasg., aged 86.

Hartley.—On Feb. 27, John Whittam Hartley, M.B. Vict., late of the West African Medical Service, aged 65.

Hubert.—On March 5, at Chelsea, William Henry de Bargue Hubert, B.A. Camb., M.R.C.P.

Ingram.—On March 4, at Devonport, John Ingram, M.B.E., M.B. Aberd.

Molyneux.—On March 2, at Kew, John Francis Molyneux, M.D. Brux., M.R.C.S., aged 90.

Newmarch.—On March 1, at Worthing, John Henry Newmarch, M.B. Camb., M.R.C.P.

Olver.—On March 7, Richard Sobey Olver, M.R.C.S.

Stewart.—On March 6, Walter Grahame Stewart, M.B.E., M.B. Lond.

Thorp.—On March 7, at Harrogate, Henry Carter Thorp, M.B. Camb., aged 74.

Todd.—On March 6, Aldred Bertram Slingsby Todd, M.B. Leeds.

Appointments

Calvey, E. M., M.R.C.S.: asst. tuberculosis officer, and Coventry Joint Committee for Tuberculosis.

Elliott, O. C., D.S.C., M.D. Birm.: asst. school M.O., County Council.

Evans, G. C. D., M.B. Wales, B.SC., D.M.R.: chief radiothe. South Wales and Monmouthshire Joint Cancer Committee.

Grimaldi, P. R. B., M.R.C.S., D.L.O.: surgeon i/c ear, nose, and throat department, Royal Isle of Wight County Hospital.

Hendtlass, R. F., M.R.C.S., D.M.R.T.: asst. radiotherapist, Royal Northern Hospital and Prince of Wales Hospital joint radiotherapy centre.

Keall, J. H. H., M.D., B.PHARM. Lond.: pathologist, Bromley and District Hospital, Kent.

Landon, J. J., M.B. Camb.: asst. school M.O., City of Birmingham education department.

Marshall, T. S., M.R.C.S.: regional blood-transfusion officer, Leeds.

O'Donnell, R. F., M.B., B.SC. N.U.I.: pathologist, Royal Victoria and West Hants Hospital, Bournemouth.

Pierse, D. J., M.CH. N.U.I., D.O.M.S.: ophthalmic surgeon, South Eastern Hospital for Children, Sydenham.

Prior, A. P., M.B. Sydney: county pathologist, Warwickshire.

Proctor, S. S., M.D. Aberd.: M.O.H. and asst. school M.O., Salisbury, Wilts.

Rees, Harland, B.M. Oxfd, F.R.C.S.: surgeon to outpatients, Hampstead and North-West London Hospital.

Rose, Doris, M.R.C.S., D.O.M.S.: asst. ophthalmic surgeon, Princess Alice Memorial Hospital, Eastbourne.

Steed, G. R., M.D. Lond., M.R.C.P.: physician, City General Hospital, Plymouth.

Sturtridge, G. S., M.B. Melb., M.R.C.O.G.: consultant asst. obstetrician and gynæcologist, General Hospital, Northampton.

Thomas, A. J., M.B., B.SC. Wales, M.R.C.P., D.P.H.: resident consultant physician, Llandough Hospital, Cardiff.

Thompson, N. J. W., M.B. Belf., D.P.H.: asst. M.O., St. Helens.

The Middlesex Hospital, London:

Hart, E. W., M.B.E., M.D. Camb., M.R.C.P., D.C.H.: physician i/c children's department.

Kelham, Geoffrey, M.B. Camb., D.M.R.E.: jun. asst. radiologist (diagnostic).

West London Hospital, Hammersmith:

Burge, H. W., M.B.E., M.B. Lond, F.R.C.S.: general surgeon.

Hindenach, J. C. R., M.D. N.Z., F.R.C.S.: orthopædic surgeon.

The Queen Elizabeth Hospital for Children, Hackney Road, London:

Cowan, H. A., F.R.C.S.E., D.L.O.: ear, nose, and throat surgeon.

Hodson, C. J. C. G., M.B. Lond., D.M.R.E.: radiologist.

Howarth, Elizabeth, M.R.C.S., D.M.R.E.: radiologist.

St. John's Hospital, Lewisham:

Barlow, D. S. M., M.S. Lond., F.R.C.S.: consultant in thoracic surgery.

Eckhoff, N. L., M.S. Lond., F.R.C.S.: consultant in plastic surgery.

Howkins, John, M.D., M.S. Lond., F.R.C.S., M.R.C.O.G.: gynæcologist.

Hughes, K. E. A., M.R.C.S.: pathologist.

Wass, S. H., M.S. Lond., F.R.C.S.: surgeon.

Willesden Corporation:

Beeston, John, G.M., M.B., D.P.H.: deputy M.O.H.

Dunsby, Cissie, M.B. N.U.I.: asst. M.O.

Jones, Esther, M.R.C.S.: asst. M.O.

Lycett, O. D. L., M.B. Lond., D.P.H.: asst. M.O.

Snow, Angèle, M.B. Lond.: asst. M.O.

London County Council:

Second Asst. M.O.s in Mental Health Services:

de Bastarrechea, M.B. Lpool, D.P.M.: Friern Hospital.

Blair, R. A., M.B. Lond., D.P.M.: Banstead Hospital.

Bridger, W. E. W., M.D. Lond., D.P.M.: Bexley Hospital.

Coffey, Bridget, M.B. N.U.I., D.P.M.: Tooting Bec Hospital.

Edwards, A. M., M.B. Lond., D.P.M.: St. Bernard's Hospital.

Rae, G. E., L.M.S.S.A.: Bexley Hospital.

Rollin, H. R., M.B. Leeds, D.P.M.: Cane Hill Hospital.

Sanders, Marjorie, M.B. Edin., D.P.M.: St. Francis' Mental Observation Unit.

Middlesex County Council:

Bigby, Mary, M.D. Lond., M.R.C.O.G.: obstetrician and gynæcologist, Central Middlesex County Hospital.

Patrick, H. F., M.R.C.S., D.A.: anæsthetist, Chase Farm Hospital.

Porter, R. J., M.B. Camb., M.R.C.P.: physician, Central Middlesex County Hospital.

Talbot, R. J. F. L., F.R.C.S.E., D.PHYS.M.: director, department of physical medicine, Hillingdon County Hospital.

Kent County Public Health Department:

Sharvelle, Doris, M.R.C.S., D.P.H.: asst. county M.O.H.

Wallace, G. P., M.B. Aberd.: asst. county M.O.H.

Cumberland Infirmary, Carlisle:

Hill, R. M., M.D. Edin., F.R.C.S.E.: surgeon.

Neill, A. G. C., M.B. Edin., F.R.C.S.E.: asst. surgeon.

Royal Salop Infirmary, Shrewsbury:

Grant, G. H., B.M., B.SC. Oxfd: pathologist.

Jones, A. C., M.B. Lond.: bacteriologist.

St. James's Hospital, Leeds:

Feather, D. B., M.B. Leeds: surgeon.

Jackson, E. W., M.D. Leeds: physician.

Stockton and Thornaby Hospital, Stockton-on-Tees:

Dickson, D. C., M.B. St. And., F.R.C.S.E.: senior surgeon.

Hunter, N. M., M.B. Edin.: senior surgeon.

Marshall, R. M., M.B. Edin., F.R.C.S.E.: asst. ear, nose, and throat surgeon.

Parker, Gilbert, M.B. Aberd., F.R.C.S.E.: asst. surgeon.

Travers, E. H., M.B. Edin., F.R.C.S.: asst. surgeon.

Notes and News

EXPENSES OF ILLNESS IN DOCTORS' FAMILIES

THE London Association for Hospital Services Ltd., which is sponsored by King Edward's Hospital Fund, has issued a leaflet presenting to doctors its "hospital service plan" providing against charges for medical and surgical treatment in hospitals or nursing-homes anywhere in Great Britain or abroad. For one person the annual standard subscription is £2 12s. and the maximum is £5 4s.: a subscriber with one adult and three or more child dependants would pay a standard subscription of £5 5s. or a maximum subscription of £10 10s. The standard benefits include weekly maintenance charges (up to six weeks' annually) of £6 6s. while the maximum benefit is £12 12s. a week. Other benefits include physicians' fees, operation fees, and payments for radiodiagnostic, pathological, and bacteriological investigations and radiotherapy, but certain forms of illness (e.g., pulmonary tuberculosis) are specifically excluded, and benefits are not obtainable till six months after joining. Subscribers must be under 60 years of age, but enrolments may continue after that age. When doctor-members or their dependants are patients, the benefits allowed for medical and surgical fees may be paid direct to the surgeons and physicians who have given the treatment, not as a fee but as a gift, and the association finds that this procedure is often a satisfactory solution to the problem of acknowledging the help of professional colleagues.

In relation to the benefits offered the rates of subscription are low, and this is possible because no profit is to be made. The plan is open to all members of the medical profession, wherever they reside, and it will make a strong appeal to many of us. Further information may be had from the secretary of the association, 10, Old Jewry, E.C.2.

AMBULANCES FOR ALL

AFTER the 1914–18 war the British Red Cross Society and the Order of St. John set up the Home Ambulance Service which has done such good work ever since. During the 1939–45 war new editions of the register of ambulance stations could not be printed, but the 1946 edition has now appeared, giving addresses and telephone numbers of the many stations, housing some 1000 ambulances among them, in England, Wales, Northern Ireland, the Channel Isles, and the Isle of Man. Under the National Health Service Act ambulance transport arrangements are permitted between local authorities and voluntary organisations; so the service is likely not only to continue but to develop. The ambulances are bought by the Order and the Society, and the responsibility of running, housing, and maintaining them is undertaken by voluntary workers. Maintenance costs are covered in various ways. In most cases a charge is made for the use of the ambulance, but where the patient cannot afford to pay he is carried free. The usual charge is therefore calculated to cover the cost of running the ambulance with a margin sufficient to allow for such remissions to needy cases, and for a small sinking fund to meet replacements. The aim has been to put an ambulance within reach of anyone who may need it, and a glance at the register shows that this must have been largely achieved. In 1923 a mobile X-ray unit was added to the service, and during the recent war a fleet of such units was put at the disposal of the Emergency Medical Service. In 1945 the ambulances carried 364,048 patients, and by December of that year nearly 4 million patients had been carried since the service was set up. Doctors and hospitals alike will welcome this new copy of the register.

SOCIAL STRUCTURE AND DISEASE

SPEAKING in Edinburgh on Feb. 27, Prof. F. A. E. Crew, F.R.S., suggested that, in countries like this, most ill health originates in social institutions which man himself has invented.[1] The society he has brought into being is in many ways out of harmony with his biological needs. An adverse psychological communal environment is associated with an increase in chronic sickness; and even the best-organised health service might not affect the morbidity-rates so long as this adverse environment exists. One of the major tasks of the immediate present is to create a social environment that will cripple and confine nobody.

There is no doubt, said Professor Crew, that the institution of marriage is crumbling and the family grouping is breaking down; nothing is more important for the maintenance advancement of society than that the causes of marital harmony should be known and removed. The mor rates reveal the imperfections of our social structure flaws in our social policies. It is coming to be recognised disease usually springs not from a single cause but from *constellation of causes. Medicine has too long been conce* with the issuing of certificates saying that men are not fit work. All too often the work, the home, the group life, *whole way of life has not been fit for men.*

STAFFING FEVER HOSPITALS

THOUGH all hospitals have staffing troubles just now, fe hospitals are perennially faced with a special difficulty, for during epidemics they must staff crowded wards which a other seasons are nearly empty. To meet this situation the London County Council[1] have recommended that hosp aids should be appointed for part-time emergency duty in such hospitals. They are to work for not more than 12 h a week, their duties being to help in the wards and, "under close supervision," to assist the nurses. They would only be used in times of epidemics, but since it would be hard to enro them rapidly a panel of candidates will be formed in advance The appeal will probably be made through advertisements in local and evening papers, and by means of posters in Under ground stations near fever hospitals; these will draw attention to the social value of the work and to the fact that volunteers will only be called on in an emergency and for a short time.

IODISED VITAMIN TABLETS

A SMALL amount of potassium iodide has now been added to the vitamin A and D tablets issued to expectant mothers at antenatal clinics. Each tablet now contains 4000 I.U. of vitamin A, 800 I.U. of vitamin D, 230 mg. of sodium calcium phosphate, and 0·13 mg. of potassium iodide. The addition has been made in the hope of lowering the incidence of simple goitre in expectant mothers.

EXPORT OF DRUGS FROM GERMANY

THE revival of the German pharmaceutical industry is considered in an article in the *Pharmaceutical Journal* for Feb. 22 by Mr. F. B. Royal, M.P.S., senior control officer of the Control Commission, chemical industries branch. Before the war, he says, Germany exported pharmaceuticals valued at £12 million—a far greater volume, allowing for depreciation in money, than Britain's 1946 figure of *£12,800,000. In the British zone,* where about half the industry is situated, the yearly output is now valued at about £14 million, and a substantial part of this has already been earmarked for export, though the policy in regard to trade-mark names for export has still not been settled. "We have done our utmost," Mr. Royal says, "to oppose the export *of pharmaceuticals in small packs* under trade names, but the desire to make Germany self-supporting by 1949 will, I fear, override any section trade interest in this country."

GENEVA AND HAGUE CONVENTIONS

IN view of the resolution, passed at a preliminary conference of red-cross societies,[2] to revise the *Geneva Convention*, the International Red Cross Committee is conferring this month with the Comité International de Médecine et de Pharmacie Militaires to discuss the latter's proposals regarding this revision. Past events leading up to the present situation are reviewed by Général-Major Médecin J. Voncken,[3] who points out that the terms of not only the Geneva Convention concerning land operations, but also the two Hague Conventions, one concerning sea warfare, the other fixing the customs of war, have been *hopelessly outstripped* by the development of modern methods of waging war, notably aerial bombing. All three conventions, the Comité International de Médecine et de *Pharmacie Militaires suggests,* should be superseded by a single new convention covering war waged on land, at sea, and in the air.

The film *Your Children and You*, discussed by a peripatetic correspondent on Feb. 8 (p. 231), can be obtained from the Central Film Library, 16 and 35 mm., *sound, 28 minutes*; directed by Brian Smith with the Realist Film Unit.

iversity of Oxford

On March 1 the following degrees were conferred:

D.M.—W. E. Gibb.
B.M.—Elizabeth M. C. Dyke.

niversity of Cambridge

On Feb. 15 and March 1 the following degrees were nferred:

M.D.—John Aspin, D. M. Baker, G. F. Barran, E. D. H. Cowen, . P. Dick, F. S. A. Doran, M. A. Rugg-Gunn, J. F. Stokes, C. C. homas, J. C. Waterlow, P. H. Willcox, G. H. Wooler.

M.B., B.Chir.—* A. P. Baker, * G. T. F. Braddock, * J. A. S. orman, * Robert Marshall, * R. H. B. Mills, A. G. Norman, Donough O'Brien, * T. C. L. Parry, * Arnold Pines, * D. J. Watt, M. E. E. White.

* By proxy.

On March 15 a grace will be submitted to the senate that ie honorary degree of doctor of science be conferred upon ir Edward Mellanby, F.R.S., secretary of the Medical Research ouncil.

Dr. Joseph Marks and Dr. E. D. H. Cowen have been ppointed to Elmore medical research studentships.

Prof. T. R. Elliott, F.R.S., has been elected an honorary llow of Trinity College.

Jniversity of Leeds

Dr. F. S. Fowweather has been appointed to the new chair f chemical pathology, with effect from Oct. 1, 1946.

Dr. Fowweather originally trained at Liverpool as a chemist, raduating B.SC., with first-class honours in chemistry, in 1914, nd M.SC. in 1915. In 1917 he became an associate, and in 1922 a ellow, of the Royal Institute of Chemistry. After some time in ndustrial and analytical chemistry he took up the study of medicine, nd qualified at Liverpool in 1922. For two years he was in general nedical practice until, in 1924, he was appointed lecturer in chemical athology at the university, and chemical pathologist to the General nfirmary, Leeds. He obtained the D.P.H. in 1924, and graduated .D. in 1925. In 1930 he was promoted to a readership. He became .R.C.P. in 1934, and F.R.C.P. in 1943. His chief interest, apart from hemical pathology, is in industrial medicine; he is chairman of he medical committee of the Leeds Joint Council on Industrial edicine. He is the author of a *Handbook of Clinical Chemical athology* and of numerous papers, including some on silicosis.

Royal College of Surgeons of England

A course of lectures on anæsthesia will be held at the ollege on weekdays at 6.15 P.M. from April 14 to 25, and at 5 P.M. on April 28 and 29. Further particulars may be had from he assistant secretary of the college, Lincoln's Inn Fields, ondon, W.C.2.

Royal College of Surgeons in Ireland

A postgraduate course in surgery will be held at the college from April 14 to June 6. Further information may be had from the registrar of the college, St. Stephen's Green, Dublin.

University College Hospital

Mr. A. W. McKenny Hughes, D.I.C., a member of the staff of the natural history section of the British Museum, has been appointed hon. entomologist to the hospital. During the war Mr. McKenny Hughes lectured at the Army School of Hygiene.

Scholarships for Nurses

The Hospital Saving Association will this year devote over £5000 to postgraduate scholarships for nurses training as nursing administrators, nursing dietitians, sister-tutors, superintendent health visitors, tutors to health visitors, health visitors, industrial nurses, or midwife teachers. They are open to nurses registered in the general part of the State register who have graduated in a hospital within the area of King Edward's Hospital Fund for London, and they will be awarded on the results of a competitive examination. Particulars may be had from the director in the education department, Royal College of Nursing, 1A, Henrietta Place, London, W.1.

Planning Under 1939 Cancer Act

The period for submission of plans under this Act has been extended to March 31, 1948. A Ministry of Health circular recalls that until the National Health Service Act comes into operation local authorities have a statutory obligation to make and submit for approval suitable arrangements for the treatment of cancer. The Minister, while recognising the undesirability of setting up joint boards at this stage, emphasises the importance of efficient interim arrangements, which should be suitable for merging into the new hospital services; and it is suggested that plans already approved or proposed should be reviewed to see whether modification is needed to fit them in with these future services.

Harveian Society of London

The Buckston Browne prize for 1946 has been awar Dr. Michael Kelly, of the University of Melbourne, for essay on the Pathology and Treatment of Fibrositis.

Royal Appointment

Major-General William Foot, M.C., late R.A.M.C., has been appointed honorary physician to the King in succession to Brigadier J. S. K. Boyd, who has retired.

Association of Industrial Medical Officers

On March 28, at 2.30 P.M., in the orthopædic department of the Western Infirmary, Glasgow, Mr. Roland Barnes will give a talk on Back Injuries in Industry, followed by a clinical demonstration.

Postgraduate Lectures at Leeds

The University of Leeds postgraduate committee is holding a fortnight's refresher course for general practitioners, to begin on May 5. It has also arranged a series of clinical meetings at Leeds General Infirmary on Tuesdays at 3.15 P.M., from April 15 to July 15. Further particulars will be found in our advertisement columns.

Survey of Child Health

The Berks, Bucks, and Oxon Regional Hospitals Council is to carry out a survey of the child-health services in its area. On this survey will be based proposals for the development of these services in the new region to be established under the National Health Service Act, which is considerably larger than the council's present territory. Prof. Alan Moncrieff has been appointed chairman of the committee which will make the survey.

World Federation of Scientific Workers

Mr. J. G. Crowther, D.SC., has been appointed secretary-general designate of the federation, which was founded last year at a conference convened by the British Association of Scientific Workers. The president of the federation is Prof. F. Joliot-Curie, the high commissioner for atomic energy in France. The federation is preparing a charter of the rights and duties of scientists to serve as a guide to scientists in all countries.

New York Academy of Medicine

The centenary celebration of the academy opened with a dinner on March 6, when Prof. J. A. Ryle was the principal speaker; his subject was Social Pathology and the New Era in Medicine. In connexion with the centenary, meetings have been arranged by the sections of the academy and by a number of affiliated organisations; and five "institutes" are being held—on library methods and problems, social medicine, public health, medical education, and hospitals.

Health in U.S. Zone of Germany

A black picture of health conditions in the United States zone of Germany is painted in the latest monthly report of General McNarney, the military governor. The report, says B.U.P., speaks of increasing danger of the spread of infectious diseases, owing to the shortage of hospital beds; of the 113,461 known cases of tuberculosis in the zone, nearly 100,000 are walking the streets. It adds that rationing is beginning to affect children in the zone: "children between 8 and 15 years of age show serious weight deficiencies and some retardation of growth as evidence of the long-standing inadequacy of their food consumption."

Health Education in Northern Ireland

The activities of the Central Council for Health Education in Northern Ireland were officially launched in December when Mr. William Grant, the minister of health and local government, presided over a gathering in Belfast of delegates representing local authorities, professional groups, and voluntary organisations. The minister said he was as much concerned with the prevention as with the treatment of ill health. It was the duty of every man and woman in the country to do all they could to look after their own health as well as that of their dependants. The chairman of the central council, Mr. Henry Lesser, and the council's medical adviser and secretary, Dr. Robert Sutherland, spoke of the encouragement received from the ministry, and of the part education could play in improving the community's health. Personal contact through responsible people—parents, teachers, doctors, nurses, youth leaders, and welfare officers—was the key to success.

THE CHRONIC SICK IN HOSPITAL

A PSYCHIATRIC APPROACH

JAMES WHIGHAM AFFLECK
M.B. Glasg., F.R.F.P.S., D.P.M.
DEPUTY MEDICAL SUPERINTENDENT, OUTER GROUP OF MUNICIPAL GENERAL HOSPITALS, CITY OF LEEDS

A SURVEY of 788 chronic-sick patients was undertaken to ascertain what types are found in the wards allotted to this group. It was hoped to make suggestions to better the lot of these patients by further classification, amendment of routine, and improvement of equipment. As the great majority had been examined in the wards of an acute hospital before admission, it was assumed that the diagnosis and prognosis would generally be correct. It was felt that in wards where improvement and recovery are the exception rather than the rule, one of the chief items in life would be the mental state and attitude of the persons in the adjoining beds. Special attention was therefore given to the mentality of the patients and to arrangements for bringing special types together.

Patients were examined in five hospitals. Three admitted chronic sick only; another had also a large modern maternity unit: and the fifth had some wards for treating tuberculosis. The hospitals had 56, 100, 316, 102, and 251 chronic beds—a total of 825—and in them 788 cases were examined. In each case some facts regarding the social status and background of the individual were noted, and the physical and mental conditions assessed. The case-record from the acute hospital was generally available and gave the diagnosis on admission. Physical examination was limited to confirming this diagnosis and to determining the present state of the disease and of the patients' functional capacity—i.e., sight, speech, hearing, walking, &c. A nurse who knew the patients was always present to give information about habits, abilities, and behaviour. Since most of the mental abnormalities were organic reaction types, the psychiatric interview tended to be limited to assessing their degree; but, where other symptoms were present, it was appropriately expanded.

Social Aspects

Women outnumbered men by almost 2¹/₂ to 1 (552 to 236, or 70·1% to 29·9%). The youngest patients were aged 15, and the oldest was 101. Almost 80% were over 65, and of the remainder more than a third were over 60. The age- and sex-incidence are shown in table I:

TABLE I—AGE AND SEX

	No. of cases	Male	Female
All age groups ..	788	236	552
65 years and over ..	628 (*79·7%*)	183 (*77·6%*)	445 (*80·6%*)
60 years and over ..	688 (*87·3%*)	204 (*86·5%*)	484 (*87·6%*)
Under 65 years ..	160 (*20·3%*)	53 (*22·4%*)	107 (*19·4%*)
Under 60 years ..	100 (*12·7%*)	32 (*13·5%*)	68 (*12·4%*)

A quarter of the patients had been in hospital less than a year—which might indicate that many were admitted to pass their last days there. Indeed the weak state on admission was often only too obvious. On the other hand, an eighth of the patients had been in hospital more than 5 years, and one woman more than 43.

Most patients came from working-class homes and had led active lives, but a section of the men, who had been taken from an old workhouse infirmary, contained a number of uncompromising ne'er-do-wells whose habits and language made accommodation among ordinary people difficult.

Most cases obviously required constant nursing of a type unobtainable at home. Several had been looked after at home until some war circumstance—e.g., a daughter taking up war work—made it impossible. Many so settled in hospital will not return home; housing is more difficult, and many families are not inclined to resume the burden of an invalid. Some families may be taking an unnecessary and unfair advantage of the public facilities; on the other hand relief has been granted to many deserving it. Mental and psychosomatic disorders in unmarried women who have given many years (consciously willing but unconsciously rebelling) to the nursing of a parent are commonly seen in psychiatric practice, and the physical effects on the young wife who tries to run both her own and her sick parent's home may be equally unfortunate. The patient in many cases does not understand the family's point of view, with unhappy results for all concerned, though many independent invalids adjust themselves philosophically to hospital. Special visiting facilities, including the admission of children, are appreciated by chronic hospital invalids, old and young, and may help to prevent the invalid from assuming that he is unwanted.

It is interesting to compare the marital status of this group with the group of old people on poor relief though not in hospital studied by Curran et al. (1946). In the present study, as in theirs, a large proportion of both sexes were widowed, but in this group there was a much larger proportion of single people (table II). The presence of a high proportion of widowed and single people in hospital compared with those married is not surprising, but it may also help to explain the continued presence of some persons who were not really ill though unable to look after themselves in their own homes.

TABLE II—MARITAL STATUS

	Curran et al. (1946)	Present study
Widowed women ..	507 of 728 (*69·6%*)	273 of 400 (*59·3%*)
Widowers	95 of 273 (*38·4%*)	79 of 200 (*34·5%*)
Single women ..	68 of 728 (*9·3%*)	105 of 400 (*26·3%*)
Single men	35 of 273 (*12·8%*)	69 of 200 (*29·3%*)
Married women ..	153 of 728 (*21·2%*)	58 of 400 (*14·5%*)
Married men ..	143 of 273 (*63·4%*)	52 of 200 (*26·0%*)

The occupation of chronic-sick beds by recovered patients and by infirm old people who could be in their own homes if help was available has been commented on elsewhere (Amulree and Sturdee 1946), and was noted in the present survey to the extent of about 12% of the total cases (5·4% of the females and 6·7% of the males). Those who are in the category of infirm were able to be up for half a day and could attend to their toilet. Many were admitted to hospital in acute illness and had not recovered enough strength to look after themselves completely. Hostels and home-helps are required for such cases, but are not available for all. Meanwhile the presence of the recovered and infirm cases in hospital lengthens the waiting-list for chronic beds but to some extent relieves the burden of the nurses.

Physical Disorders

Table III summarises the types of disorder responsible for the retention of the patients in hospital.

TABLE III—PHYSICAL DISORDERS

	236 Males	552 Females
Senile weakness	47 (*19·9%*)	80 (*14·0%*)
Cardiovascular disorders	22 (*8·5%*)	62 (*10·2%*)
Central nervous disorders	78 (*33·0%*)	169 (*30·6%*)
Respiratory disorders	24 (*9·6%*)	33 (*5·9%*)
Alimentary disorders	9 (*3·6%*)	8 (*1·4%*)
Genito-urinary disorders	2 (*0·8%*)	4 (*0·7%*)

London College of Osteopathy

A nine-month course in osteopathy is to be held at this college, beginning in October. Only qualified medical men and women will be accepted. Further information may be had from the secretary, 25, Dorset Square, N.W.1.

End of the Scarce Substances Orders

The last remaining Scarce Substances Order, under which alternatives could be dispensed when the liquid extract or tincture of ipecacuanha was prescribed, was revoked on March 1.

Great Ormond Street Dining Club

The 19th annual dinner will be held at the Savoy Hotel, on Friday, April 11, at 7 P.M., when Dr. Harold Sington will be in the chair. Members who wish to attend are asked to communicate with the honorary secretary, at the Hospital for Sick Children, Great Ormond Street, London, W.C.1.

American Research into Diseases of the Aged

The National Institute of Health's programme of research into diseases of the aged is now being resumed. One unit, under Dr. Nathan Shock, is starting work on kidney diseases in Baltimore City Hospital. Another group, B.U.P. reports, is to study the processes of ageing; a thousand or more healthy adults, aged from 30 to 90, will undergo tests at intervals of one, two, or five years.

Australian Medical Honours

The King has made the following appointments to the Royal Victorian Order:

M.V.O.

ASHLEIGH O. DAVY, M.B. Sydney, F.R.A.C.S.
LORIMER F. DODS, M.D. Sydney, F.R.A.C.P.
Prof. B. T. MAYES, M.B. Sydney, F.R.A.C.S., F.R.C.O.G.
Group-Captain H. R. G. POATE, M.B. Sydney, F.R.C.S., F.R.A.C.S., R.A.A.F.

Return to Practice

The Central Medical War Committee announces that Mr. Harold Burge, M.B.E., F.R.C.S., has resumed civilian practice at 14, Upper Harley Street, London, N.W.1 (Welbeck 4824).

Medical Society of London

At the 167th annual dinner, on March 6, Lord Oaksey, who as Lord Justice Lawrence presided over the Nuremberg trials, spoke of these trials as a vindication of international law. Without laws between the nations, which necessarily limited their sovereignty, what was to become of the world? Since the 14th century at least there had been rules of war, and Germany had been one of the 63 nations party to the Kellogg Pact which renounced war as an instrument of policy. The charter of 1945 represented a great step forward in the progress of international law. Thanks to the seizure of vast numbers of documents, the prosecution's case against the Nazi leaders had been based almost entirely on what they themselves had said, and it would now be difficult to deny their guilt. To say that soldiers and officials could not be held responsible for what they did under orders was itself a denial of international law.

Sir Philip Manson-Bahr, the president, spoke of Lettsom's injunction to the society to continue in amity and good fellowship—an injunction applicable today to the whole profession. It was right that we should consider and debate the place of medicine in the world, but it was wrong to introduce pure politics into our professional life, setting one man against another. Mr. Dickson Wright, who proposed The Guests, recalled that Lettsom was the last and only surviving member of a family consisting of seven sets of twins. He compared the presidents of the three Royal Colleges, in their new-found unity, to the three bears who said "who's been at *our* porridge?" or even "who's been at the Minister's porridge?" Lord Moran, in reply, said that the society's great past was associated with individual effort. The change which most disturbed him in recent times was the dread of responsibility and the dread of public opinion which had invaded every department of life.

B.C.G. is to be used in New York State; the programme, according to B.U.P., is to be established by Dr. Konrad Birkhaug, the Norwegian authority.

CORRIGENDUM: *Thyroid and Cold Sensitivity.*—In Dr. S. L. Simpson's letter last week the reference was to M. L. Turner (not Tanner).

Diary of the Week

MARCH 16 TO 22

Monday, 17th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Prof. F. Wood Jones, F.R.S.: Visceral Outlet of Hind End.
5 P.M. Mrs. E. K. Dawson, M.D.: Genesis and Spread Mammary Cancer.

HUNTERIAN SOCIETY
7.15 P.M. (Pimm's, 3, Poultry, E.C.2.) Sir Reginald Watson-Jones, Dr. J. B. Mennell: Sprains and Strains.

Tuesday, 18th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. F. Avery Jones: Hæmatemesis and Melæna. (Goulstonian lecture.)

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Mrs. Dawson: Diagnosis and Prognosis of Mammary Cancer.
5 P.M. Prof. H. A. Harris: Clinical Anatomy of the Chest.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. General meeting of fellows.
8.15 P.M. *Pathology.* Prof. A. W. Downie, Dr. J. A. Dudgeon, Prof. S. P. Bedson, F.R.S., Dr. F. O. MacCallum: The Laboratory Diagnosis of Virus Infections.

CHADWICK LECTURE
5.30 P.M. (Westminster Hospital medical school, 17, Horseferry Road, S.W.1.) Prof. W. M. Frazer: A Medical Pioneer in Sanitation.

ROYAL PHOTOGRAPHIC SOCIETY, 16, Princes Gate, S.W.7
6.30 P.M. *Medical Group.* Dr. R. G. W. Ollerenshaw: Production of the Surgical Teaching Film.

EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mr. E. B. Ford: Recent Advances in Genetics.

LONDON SCHOOL OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. Henry MacCormac: Principles of Treatment.

Wednesday, 19th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. C. L. Oakley: Toxins of *Clostridium welchii* and *Cl. œdematiens.*
5 P.M. Professor Harris: Clinical Anatomy of the Abdomen.

ROYAL SOCIETY OF MEDICINE
5 P.M. *Comparative Medicine.* Sir Edward Salisbury, F.R.S., Mr. Ian Galloway, D.SC., Mr. John Hammond, F.R.S.: The Span of Life.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. Noel Harris: The Health of the Mind.

Thursday, 20th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. Avery Jones: Hæmatemesis and Melæna. (Goulstonian lecture.)

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Professor Oakley: Toxins of *Cl. welchii* and *Cl. œdematiens.*
5 P.M. Professor Harris: Clinical Anatomy of the Abdomen.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE
8 P.M. (Royal Army Medical College, Millbank, S.W.1.) Laboratory meeting.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH
8 P.M. Joint discussion at Glasgow with the Royal Medico-Chirurgical Society of Glasgow: that the Nation is tending to become Disease-conscious rather than Health-conscious.

Friday, 21st

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. Cuthbert Dukes: Tumours of the Rectum and Colon.
5 P.M. Prof. John Kirk: Anterior Abdominal Wall.

ROYAL SOCIETY OF MEDICINE
8 P.M. *Obstetrics and Gynæcology.* Mr. Rufus Thomas, Mr. J. H. Peel, Mr. C. MacIntosh Marshall, Miss Katharine Lloyd-Williams, Dr. C. J. Massey Dawkins, Dr. J. N. Cave: Anæsthesia for Cæsarean Section.
8 P.M. *Radiology.* Dr. J. F. Brailsford: Bone Tumours.

FACULTY OF RADIOLOGISTS
2.30 P.M. Diagnosis Section Meeting (Royal College of Surgeons). Dr. S. Cochrane Shanks: Hiatus Hernia.

BRITISH INSTITUTE OF RADIOLOGY
5 P.M. (French Institute, Queensberry Place, S.W.7.) Dr. F. Baclesse: Cancer of the Larynx.

Saturday, 22nd

BRITISH INSTITUTE OF RADIOLOGY
10.15 A.M. Prof. D. W. Smithers: presidential address.
11.20 A.M. Papers on carcinoma of the cervix.

Dr. W. S. Flowers has left England to join Sir Clutha Mackenzie on a St. Dunstan's mission to advise the Chinese government on the training of blinded soldiers and civilians. Dr. Flowers has been chief medical representative on the Red Cross China Commission, and Sir Clutha has been in charge of the St. Dunstan's training centre at Dehra Dun, for blinded Indian and Gurkha soldiers, since he established it in 1943.

Table VI shows the different types of mental disorders. Among the clinical types of senile dementia found in these wards the apathetic one described above predominated. The confused and restless conditions associated by Howell (1945) with progressive cerebral ischæmia were observed and nursed when possible in cot beds. The more obvious results of cerebral arteriosclerosis, such as hemiplegia and aphasia, were observed in some cases of both types.

TABLE VI—TYPES OF MENTAL DISORDERS

	92 Males	*202 Females*	*Total 294*
Senile dementia ..	44 (*47·8%*)	123 (*60·9%*)	167 (*56·5%*)
Presenile dementia*.	14 (*15·2%*)	27 (*13·4%*)	41 (*13·9%*)
Taboparesis	4 (*4·3%*)	—	4 (*1·4%*)
Paranoid states ..	10 (*10·9%*)	13 (*6·4%*)	23 (*7·8%*)
Depression	3 (*3·3%*)	15 (*7·4%*)	18 (*6·1%*)
Neuroses	5 (*5·5%*)	8 (*3·9%*)	13 (*4·4%*)
Congenital mental defect	12 (*12·9%*)	16 (*7·9%*)	28 (*9·6%*)

* Including cases with arteriosclerosis-like symptoms, disseminated sclerosis, myxœdema, cerebral tumour, and epilepsy.

Mental disorders in the younger chronic-sick patients were also often the effect of organic brain disease. Among those between 50 and 65 years of age the dementia which may accompany arteriosclerotic hemiplegia and other hypertensive manifestations was fairly common.

That some functional states were discovered might be surprising, though the anxiety states were mostly associated with hypertension and heart disease. One outstanding case of hysterical paraplegia responded well to treatment.

Chronic delusional states with some systematisation (paranoid states) were found, especially among the deaf and the older people. These patients were often quarrelsome and regarded their attendants as accomplices in a plot to deprive them of their rights or to injure them. Some were hallucinated and others quietly grandiose.

Long periods in hospital tend to produce depression and apathy, especially among the older patients and others who have difficulty in establishing new interests to help in their adaptation to hospital life. Besides these reactions a few cases of abnormal depression were encountered, nearly all of which had originated before admission. Most had some severe environmental strain besides their chronic illness. The physical disabilities in most cases made suicidal attempts unlikely, but one cannot avoid the impression that the possibility of this event in depressed states is not sufficiently recognised.

The mentally defective group included patients with *Little's* disease and congenital syphilis and several of the patients admitted for epilepsy—which in these cases was a complication of their mental deficiency. Mental defectives and epileptics in the community who are not suitable for occupation or training present a problem which is nearly insoluble owing to the great scarcity of institutional beds. At present they must live as a burden to their families, and it is not surprising or particularly inappropriate that they are fairly numerous in the institutions for chronic sick.

TABLE VII—SENILE DEMENTIA

	Male	*Female*	*Total*
Total senile dementia	44	123	167
Of all patients ..	$\frac{44}{236}$ (*18·5%*)	$\frac{123}{552}$ (*22·3%*)	$\frac{167}{788}$ (*21·2%*)
Of mentally disordered	$\frac{44}{92}$ (*47·8%*)	$\frac{123}{202}$ (*60·9%*)	$\frac{167}{294}$ (*57·5%*)
Of organic dementias	$\frac{44}{65}$ (*67·6%*)	$\frac{123}{167}$ (*77·2%*)	$\frac{167}{232}$ (*71·6%*)

Though some psychotic patients were transferred to mental hospitals for treatment or safety, the fact that the remainder are nursed near their homes and in general hospitals is usually appreciated by their relations and friends. Their removal elsewhere could not in most cases be justified, but the existence of such a large psychiatric population in some of our general hospitals is not generally appreciated, though there is a general impression that cases of senile dementia are so accommodated. Table VII shows the distribution of senile dementia.

If the psychiatric disorders are surveyed from the prognostic angle, the same mixture of recovery, long-term improvement, and incurability is found as among the physical disorders. The proportion of potential recoveries is much less, but nevertheless they do exist.

Classification

Many of the regional survey commissioners commented on and deplored the absence of classification in the arrangements for these patients (see Nuffield Provincial Hospitals Trust 1946). The ideal would be to have separate accommodation for cases of each type of prognosis and for the aged group, thus:

(1) Long-term cases (recovery anticipated) in special rehabilitation hospitals.
(2) Incurable cases in best present accommodation for chronic sick.
(3) The aged sick in the geriatric hospital department, with acute departments.
(4) The infirm in hostels or "eventide homes."

Meanwhile, however, the pressure on acute beds is so great that a patient whose illness is going to be lengthy must be accommodated elsewhere whenever this seems reasonably possible. The result is that the patient sometimes passes from one doctor and hospital to another and even in some cases completes his recovery in a chronic-sick ward. In the attempt to contend with this situation a system of classification has been applied (table VIII). The fundamental clinical subdivision is the segregation of those with major disorders of the mind. After this, the younger patients are nursed separately from the aged, and special arrangements are made for the types with social defects (incontinence, epilepsy, &c.). These arrangements are often made by the ward sisters, but to be effective they must be planned and supervised by someone with wider authority. When the general scheme has been developed, rearrangement of patients must be expected and be regarded as part of the right of the chronic sick. Potential recoveries have not yet been separated, but physiotherapy is available.

TABLE VIII—CLASSIFICATION

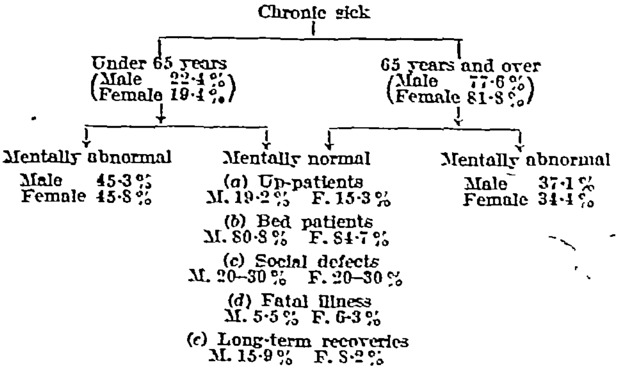

Table VIII indicates the relative distribution of some of the classes for whom special arrangements may be needed.

Management

ACCOMMODATION

Size of Units.—The number of beds in a chronic medical unit is unimportant if there are enough subdivisions in the accommodation to allow proper classification of the ness might have been equally appropriate; some of them had senile dementia, with presumably a degeneration of the cerebral cortex which would also be a factor in the weak muscular state. Nearly a third of all cases had a lesion of the central nervous system. As might be anticipated, the degenerations and cardiovascular accidents associated with old age were very much in evidence: 15% of the patients had hemiplegia. Osteoarthritis occurred in 11% of the female cases and in 5% of the men, whereas rheumatoid arthritis (3·9%) was almost limited to females. Chronic bronchitis and its complications were seen in nearly 10% of the patients. Other conditions occurring in more than 4% of cases were carcinoma, epilepsy, and fractures of the femur. Among the younger patients cases of relatively rare diseases of the central nervous system presenting interesting symptoms and signs were found, tucked away far from the path of even the most enthusiastic student. The familial and hereditary nature of some of these diseases was made obvious by the presence of brothers and sisters with the same conditions in the same hospital. Unusual conditions, such as diaphragmatic hernia and hermaphroditism, were present incidentally.

The academic classification given above, however, is less important from the point of view of routine hospital work than the functional disabilities (table IV). Blindness, feeding difficulties, incontinence, &c., are the matters of immediate import to the chronic-sick patient and his nurse.

TABLE IV—FUNCTIONAL DISABILITIES

	Males	*Females*
Sight:		
Blindness	19 (8·1%)	25 (4·5%)
Poor sight..	19 (8·1%)	16 (2·9%)
Hearing:		
Deafness	17 (7·2%)	41 (7·8%)
Poor hearing	19 (8·1%)	31 (5·6%)
Speech (aphasia and dysarthria) ..	35 (14·8%)	48 (8·7%)
Inability to feed self	32 (13·6%)	38 (6·8%)
Walking:		
Incapable of walking	80 (33·9%)	230 (41·7%)
Requiring help	108 (45·8%)	247 (44·7%)
Incontinence:		
Of urine	20 (8·5%)	58 (10·5%)
Double incontinence	26 (10·6%)	63 (11·4%)
Occasional incontinence ..	9 (3·8%)	12 (2·2%)
Fits	9 (3·8%)	27 (4·4%)

An examination of the disorders found, from the point of view of prognosis, reveals that the following types of patient can be admitted:

(1) Incurable.
(2) Long-term cases—e.g., some cardiac, chronic bronchitis, hemiplegia, genito-urinary and skin patients—in whom recovery is possible but uncertain.
(3) Recoveries.

Included in these types are patients with diseases due to old age who may recover or become infirm or incurable.

Mental Disorders

Though patients were not admitted primarily for mental symptoms, the incidence of mental disorders was high (table V).

TABLE V—INCIDENCE OF MENTAL DISORDERS

	Total	*Male*	*Female*
All patients ..	$\frac{294}{788}$ (37·3%)	$\frac{92}{236}$ (38·9%)	$\frac{202}{552}$ (36·6%)
Aged 65 and over..	$\frac{221}{628}$ (35·2%)	$\frac{68}{188}$ (37·1%)	$\frac{153}{445}$ (34·4%)
Aged under 65 ..	$\frac{73}{160}$ (45·6%)	$\frac{24}{53}$ (45 3%)	$\frac{49}{107}$ (45·8%)

Of the 788 patients 294 (37·3%) showed obvious mental symptoms. The sexes were equally affected. Among those aged 65 and over, 35% showed symptoms. It is perhaps more surprising to record that 45% of the younger group displayed serious disorders. In 80% of cases the condition was apparently due to organic change in the brain. The remaining 20% (60 patients) included 28 mental defectives and 32 others whose psychosis or neurosis was of a more functional type. The disorders were mild in the sense that they did not lead to gross abnormality of behaviour or thought, but the patients affected usually could not carry on a normal conversation and join or enjoy communal activities or interests. The following cases illustrate the types of mental disorders found:

CASE 1.—Apathetic senile dementia. A widow, aged 85, had been in hospital for six years. She had been admitted to the acute hospital for senile weakness and chronic ulceration of the right leg, which was epitheliomatous. She had average sight but poor hearing. She could feed herself but could not walk. She had double incontinence and had to be "changed" regularly. Mentally she was quiet. She was sometimes restless at night and dirty in her habits. Her speech was normal but her talk confused. She never spoke unless addressed. She was apathetic, showed no interest in her surroundings, and appeared to eat automatically. She was completely disoriented and appeared to be unable to remember anything but her name.

CASE 2.—Restless senile dementia. A widow, aged 79, had been in hospital three months. She had been admitted from the acute hospital as a case of cerebral thrombosis. She had average sight and hearing. She could walk but needed help to avoid falling. She was often incontinent. She was restless and would often come out of bed and proceed along the ward holding on to the other beds. She required assistance with her meals, as she ate spasmodically and would play with the food. At night she would talk and sometimes wished to walk. She was confused in her ideas but was keen to converse and could give her name and address and age fairly accurately, though not every time she was asked. Memory for recent events was poor.

CASE 3.—Presenile dementia following hemiplegia. A labourer, a widower aged 59, had been admitted with hyperpiesia and right hemiplegia of three years' duration. Sight, hearing, and speech were normal. He could feed himself but was doubly incontinent. He was quiet, spoke only when addressed, and was completely apathetic. His memory was very poor, and he was disoriented for time and place.

CASE 4.—Presenile dementia due to disseminated sclerosis. A married man, aged 44, a sheet-metal worker, had been admitted three years ago with disseminated sclerosis, giving paraplegia and incontinence. His sight and hearing were normal but there was some difficulty in speech. He could feed himself. He was quiet and ready to converse but this was difficult and slow because the speech was dysarthric, and there was some difficulty in thinking. His mood was amiable and tended to euphoria. His memory was poor, and he could not give the day or month. His thoughts were rather simple and facile and sometimes confused.

Forgetfulness of variable degree is normal in senescence. If a man lives long enough he will become forgetful. It is of the same nature as the stiffening of aged joints and the weakening of aged muscles. Some difficulty in recalling recent events was observed in patients between 65 and 70, whereas apparent complete lucidity was observed in one or two over 90. Forgetfulness by itself was not regarded as senile dementia, nor was the state of apathy with loss of interest in time and in day-to-day events which was often present in those old people in hospital. This distinction, however, is artificial, in the sense that it separates only two stages of the same pathological process. It might have been more accurate to have labelled these cases "simple senile deterioration" and added them to the total of mental disorders. Cases of this type progress to dementia when the patients become disoriented for time and place and person, show complete apathy to their surroundings (though usually retaining some interest in meals), and become incontinent. There were 86 patients (37 males and 49 females) in the forgetful category.

Table VI shows the different types of mental disorders. Among the clinical types of senile dementia found in hese wards the apathetic one described above prelominated. The confused and restless conditions associated by Howell (1945) with progressive cerebral ischæmia were observed and nursed when possible in cot beds. The more obvious results of cerebral arteriosclerosis, such as hemiplegia and aphasia, were observed in some cases of both types.

TABLE VI—TYPES OF MENTAL DISORDERS

	92 Males	*202 Females*	*Total 294*
Senile dementia ..	44 (*47·8%*)	123 (*60·9%*)	167 (*56·8%*)
Presenile dementia*.	14 (*15·2%*)	27 (*13·4%*)	41 (*13·9%*)
Taboparesis	4 (*4·3%*)	—	4 (*1·4%*)
Paranoid states ..	10 (*10·9%*)	13 (*6·4%*)	23 (*7·8%*)
Depression	3 (*3·3%*)	15 (*7·4%*)	18 (*6·1%*)
Neuroses	5 (*5·5%*)	8 (*3·9%*)	13 (*4·4%*)
Congenital mental defect	12 (*12·9%*)	16 (*7·9%*)	28 (*9·6%*)

* Including cases with arteriosclerosis-like symptoms, disseminated sclerosis, myxœdema, cerebral tumour, and epilepsy.

Mental disorders in the younger chronic-sick patients were also often the effect of organic brain disease. Among those between 50 and 65 years of age the dementia which may accompany arteriosclerotic hemiplegia and other hypertensive manifestations was fairly common.

That some functional states were discovered might be surprising, though the anxiety states were mostly associated with hypertension and heart disease. One outstanding case of hysterical paraplegia responded well to treatment.

Chronic delusional states with some systematisation (paranoid states) were found, especially among the deaf and the older people. These patients were often quarrelsome and regarded their attendants as accomplices in a plot to deprive them of their rights or to injure them. Some were hallucinated and others quietly grandiose.

Long periods in hospital tend to produce depression and apathy, especially among the older patients and others who have difficulty in establishing new interests to help in their adaptation to hospital life. Besides these reactions a few cases of abnormal depression were encountered, nearly all of which had originated before admission. Most had some severe environmental strain besides their chronic illness. The physical disabilities in most cases made suicidal attempts unlikely, but one cannot avoid the impression that the possibility of this event in depressed states is not sufficiently recognised.

TABLE VII—SENILE DEMENTIA

	Male		*Female*		*Total*	
Total senile dementia	44		123		167	
Of all patients ..	$\frac{44}{236}$	(*18·8%*)	$\frac{123}{552}$	(*22·3%*)	$\frac{167}{788}$	(*21·2%*)
Of mentally disordered	$\frac{44}{92}$	(*47·8%*)	$\frac{123}{202}$	(*60·9%*)	$\frac{167}{294}$	(*57·5%*)
Of organic dementias	$\frac{44}{65}$	(*67·6%*)	$\frac{123}{167}$	(*77·2%*)	$\frac{167}{233}$	(*71·6%*)

The mentally defective group included patients with Little's disease and congenital syphilis and several of the patients admitted for epilepsy—which in these cases was a complication of their mental deficiency. Mental defectives and epileptics in the community who are not suitable for occupation or training present a problem which is nearly insoluble owing to the great scarcity of institutional beds. At present they must live as a burden to their families, and it is not surprising or particularly inappropriate that they are fairly numerous in the institutions for chronic sick.

Though some psychotic patients were transferred to mental hospitals for treatment or safety, the fact that the remainder are nursed near their homes and in general hospitals is usually appreciated by their relations and friends. Their removal elsewhere could not in most cases be justified, but the existence of such a large psychiatric population in some of our general hospitals is not generally appreciated, though there is a general impression that cases of senile dementia are so accommodated. Table VII shows the distribution of senile dementia.

If the psychiatric disorders are surveyed from the prognostic angle, the same mixture of recovery, long-term improvement, and incurability is found as among the physical disorders. The proportion of potential recoveries is much less, but nevertheless they do exist.

Classification

Many of the regional survey commissioners commented on and deplored the absence of classification in the arrangements for these patients (see Nuffield Provincial Hospitals Trust 1946). The ideal would be to have separate accommodation for cases of each type of prognosis and for the aged group, thus:

(1) Long-term cases (recovery anticipated) in special rehabilitation hospitals.
(2) Incurable cases in best present accommodation for chronic sick.
(3) The aged sick in the geriatric hospital department, with acute departments.
(4) The infirm in hostels or "eventide homes."

Meanwhile, however, the pressure on acute beds is so great that a patient whose illness is going to be lengthy must be accommodated elsewhere whenever this seems reasonably possible. The result is that the patient sometimes passes from one doctor and hospital to another and even in some cases completes his recovery in a chronic-sick ward. In the attempt to contend with this situation a system of classification has been applied (table VIII). The fundamental clinical subdivision is the segregation of those with major disorders of the mind. After this, the younger patients are nursed separately from the aged, and special arrangements are made for the types with social defects (incontinence, epilepsy, &c.). These arrangements are often made by the ward sisters, but to be effective they must be planned and supervised by someone with wider authority. When the general scheme has been developed, rearrangement of patients must be expected and be regarded as part of the right of the chronic sick. Potential recoveries have not yet been separated, but physiotherapy is available.

TABLE VIII—CLASSIFICATION

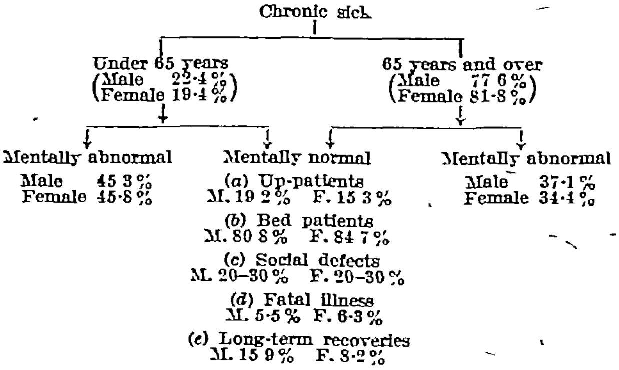

Table VIII indicates the relative distribution of some of the classes for whom special arrangements may be needed.

Management

ACCOMMODATION

Size of Units.—The number of beds in a chronic medical unit is unimportant if there are enough subdivisions in the accommodation to allow proper classification of the patients. Thus a 150-bed unit composed of 25-bed wards usually leads to the mixture of types of cases which it is desirable to separate. This has been demonstrated in our own hospitals—as a result of staff shortage which necessitated the closure of wards allocated to special types of patients. Of the patients in this survey 70% were in wards of 3–15 beds.

Admission System.—All patients should be admitted first to a hospital for acute cases and be thoroughly examined. During this time the mental state should be assessed and arrangements made to transfer the patient to the chronic ward which is suitable to his capacity, interests, and age-group. If patients are admitted directly from their homes, an admission ward or bed is required in the chronic unit so as to avoid the system whereby a new patient is placed in any available bed, irrespective of the type of ward.

Buildings.—None of our buildings were built for the purpose, but most have undergone structural adaptation and alteration to house the chronic sick. One hospital was very favourably commended in the regional survey (Eason et al. 1945) as an example of good chronic-sick accommodation. Cheerful decoration and provision of a light for each bed are two features which we insist on having in our own homes but which appear in the past to have been regarded as an unnecessary extravagance. Perhaps the most valuable item which is lacking is adequate single-room accommodation for the dying, those who have constant pain and need quiet, and those whose disease gives rise to offensive odour or unsightliness. Three single rooms for each 100 beds are the minimum required for medical reasons only. Extensive single-room units in these days of shortages of nurses and domestics are a doubtful asset.

Up-patients require day-rooms, and many who have difficulty in walking or can move about in a chair are found accommodation on the ground floor, so that they have every opportunity of getting outside. A daily change of view means a great deal to a person who is always in bed, and the use of a veranda or balcony is much appreciated.

MEDICAL STAFF

Local general practitioners or medical officers who have other duties are the usual physicians to these wards, for which they can spare too little time. It is essential that the medical officer should have access to the consultants and facilities of the acute hospital. At the same time the status, efficiency, and morale of these hospitals could be raised immediately if a visiting physician, orthopædic surgeon, and perhaps ophthalmologist of consultant rank were appointed to visit the wards regularly, though not necessarily often.

MEDICAL AUXILIARIES

Physiotherapy.—The physiotherapy generally indicated in these wards is satisfactorily given under the supervision of the trained nurses. Passive movements of limbs and the use of simple lamps can be prescribed; but, where more expert service is required, the patient is transferred to the acute hospital or to the chronic one within the same grounds.

Occupational Therapy.—The absence of activity between meals in the male wards is most noticeable in comparison with the female side, where most patients who have the use of their hands and minds are doing knitting or crochet. In spite of this, only about 20% of the female patients can engage in this activity. The mental benefits of diversional activities are so important that a special effort must be made to ensure that all who can be employed, including the men, are employed. The part-time services of an occupational therapist are desirable, so that the maximal variety of activities with expert teaching can be provided; but failing this an enthusiastic ward sister can give the necessary stimulus.

Blind Welfare.—Workers trained in this subject do good work, with the result that blind patients often receive more outside attention and corresponding benefits than those unafflicted.

Almoners are helpful and popular. It may be hoped that, when almoners are freed from financial duties by the National Health Service Act, the patients will benefit by the expansion of their social services, which might suitably include the further coordination of voluntary services with the official workers.

NURSING STAFF

Table IV summarises to some extent the special nursing duties in connexion with chronic-sick work, but there must be added to them the disorders of behaviour and lack of coöperation which accompany some of the mental states described.

The nursing of the chronic sick is perhaps the least attractive of all nursing. There is little reason why staff should be attracted to chronic work while shortage exists elsewhere. Even assistant nurses are being made welcome now in acute hospitals and in industry, with the result that many chronic hospitals have to rely more and more on their ward orderlies. Thus the domestic worker finds herself assisting the nurse in ways which make both parties wonder where the distinction lies. When the non-resident orderly does not come to work, the acute situation is heroically handled and remains unrecorded. It seems inevitable that, for some time to come, most chronic patients in hospital will need to be attended by inadequate numbers of assistant nurses aided by ward orderlies, and that those hospitals which have a satisfactory proportion of fully trained staff will be regarded as extremely fortunate. The cure for such conditions is outside the scope of any single authority, but provision of training for assistant nurses at all suitable hospitals, with allocation of teaching duties to ward sisters, should to some extent arouse interests at present absent. Lectures on simple medical and nursing psychology and demonstrations of occupational therapy should be included in the training of assistant nurses. In work for the chronic sick the usual objections to the three-shift system for nurses do not apply; so where this is desired by the staff (and the staff are available) it should be in operation.

SOCIAL DEFECTS

Blindness.—Patients are often greatly assisted by being placed beside others who are willing to act as eyes by reading to them and by commenting on the events of the day. Such virtue is not without reward, and the team-work is of value to the ward morale.

Deafness.—In the absence of an effective hearing-aid this is perhaps the most awkward problem. Its serious effect on mental health is illustrated by the fact that of the paranoid personalities a third were deaf.

Incontinence.—It is customary to nurse these cases together in so-called "changing" wards, where regular attention is given with the minimum disturbance to other patients. Since such incontinence is accompanied by, or the result of, dementia, this arrangement is usually acceptable; but it is essential to see that here also the mental state of the patient justifies inclusion in a special ward.

Postencephalitic Disabilities.—The unsightliness and dysarthria associated with many of these conditions justify some segregation. Total segregation, however, leads to injustice, as the conversational powers of so many are so limited that the less severely affected are unduly penalised. The feeding process is so slow that the nursing time-table in such wards is difficult to maintain.

Epileptics are often so quarrelsome and self-righteous that some separate accommodation is required with a separate day-room. Exceptions will be made when fits are infrequent and personality traits acceptable. Dietetic and medicinal therapeutic measures are facilitated by segregation of the group.

FATAL ILLNESSES

The admission of a cancer patient does not demand any special procedure, as many such patients for many months or even years enjoy the company of other patients. The presence of pain or any other unrelieved symptoms, however, deserves the provision of separate and quiet accommodation.

VOLUNTARY HELP

Here above all is a field relatively little explored wherein the voluntary worker can find inexhaustible outlet for energy with satisfying reward. The Red Cross Library workers are greatly appreciated. Concert parties who visit the wards of immobile patients in small groups are popular. (The voluntary society at one of our hospitals has provided a portable stage for the day-room and supplies monthly concert parties which are attended by up- and-chair-patients and relayed round the wards through the loudspeakers.) Film shows are also practicable and welcomed. Such services as letter-writing and reading can be provided for some patients, as shortage of staff makes it difficult for nurses to perform this service, which they cheerfully do in better circumstances. The patients' own relations and friends are usually loyal helpers, and they should be admitted to the wards as much as possible.

REHABILITATION, CHRONIC SICKNESS, AND THE FUTURE

Rehabilitation means essentially the prevention of chronic sickness, though it is not generally thought of in association with the type of invalid found in these hospitals. An examination of the physical conditions responsible for the presence of these patients in hospital does not suggest that many of their ultimate states could have been prevented under present conditions. When admission to a chronic-sick ward is granted, the aims of rehabilitation must be modified. Patients without gross lesions can, with help and encouragement, be prevented from becoming bedridden, and their mental faculties can be stimulated and maintained by talking, reading, radio, occupational diversions, concerts, and visitors. In these cases the aim is not always recovery but to make the patient fit to live outside hospital, either at home with some domestic help or in a hostel or home for similar people. Younger incurable patients are often more handicapped physically than older ones—e.g., some of the disseminated sclerosis and post-encephalitis groups—but a few remain who may regain connexion with the outer world by the use of some simple crafts which may bring them some remuneration.

The chronic rheumatic conditions and the effects of chronic bronchitis are two groups which might be reduced to some extent. Methods of attack on the chronic rheumatic diseases are suggested by the Medical Advisory Committee (Scotland) (1945) which recommends that there should be more hospital beds for articular rheumatism, with peripheral clinics at which specialist personnel would advise and supervise treatment. Such a scheme would ensure that admission to a chronic-sick bed was not the result of inaccessibility of expert advice and supervision.

Chronic bronchitis and its complications are at least theoretically preventable and might be largely reduced by proper rehabilitation after recovery from acute chest infections. Rehabilitation might be described as "supervised convalescence in suitable surroundings," an item which the average man is denied. For most of those about to leave hospital it is very hard even to find a place in a convalescent home. Hence the convalescence is spent in the unsatisfactory environment of the patient's home and street, and he often returns to work before health is regained. The provision of convalescent and rehabilitation accommodation within reasonable distance of the town is a necessity for each acute unit—medical or surgical. It would help to reduce the incidence of subclinical ill health which allows chronic catarrhal states to develop.

If the present chronic sick were subdivided into long-term cases and incurable, and separate accommodation were provided for the two groups, we could concentrate our knowledge and services for the benefit of those whose outlook may be doubtful.

Services such as those described above would fulfil the needs of the incurable group. The long-term cases require to be amalgamated with the ordinary convalescents and provided with a greatly extended rehabilitation service, which might include vocational training for those who need a new rôle in life. A subcommittee of the medical faculty of Leeds General Infirmary have suggested the provision of a rehabilitation village where long-term cases of all the specialties could be housed. Educational services for children, workshops for adults, occupational and physiotherapy departments, community social centres, houses, flats, and hostels for staff, and administrative offices would all be required, besides the hospital and hostel for patients. Such a scheme illustrates the extent of our needs if chronic illness is to be reduced to a minimum.

The study of diseases of the aged would be greatly assisted if, as suggested by Warren (1946), the "geriatric specialty" was developed in this country to the same extent as the pædiatric, to which it is analogous. There is already in our chronic-sick wards and hospitals a large nucleus which, if organised with appropriate acute and outpatients' departments added, might develop into one of the most important services of the future.

Summary

A survey was made of 788 cases in the chronic-sick wards of five hospitals.

The outstanding social aspects were the advanced age of most of the patients, the high proportion of widowed and single people, and the presence of many recovered cases.

Physically, lesions of the central nervous system, senile weakness, arthritis, and chronic bronchitis were the most numerous conditions.

Mental disorder was found in 294 (37·3%). In the great majority of cases this was the result of organic brain disease, though most of the common mental disorders were found.

The classification of chronic-sick patients is discussed, and some problems of medical administration connected with the accommodation of these patients in hospital are mentioned. Suggestions are made about the possibility of preventing some of the conditions, and the reorganisation required to this end.

I have to thank Prof. J. Johnstone Jervis, medical officer of health, City of Leeds, for helpful advice and criticism and permission to publish this paper; and Dr. Wm. McIntosh, medical director of hospitals, City of Leeds, for enabling me to study the cases under his care.

TREATMENT OF ANURIA FOLLOWING INTRAVASCULAR HÆMOLYSIS

RICHARD H. DOBBS
M.D. Camb., M.R.C.P.
LATE LIEUT.-COLONEL R.A.M.C.

ANURIA following extensive post-transfusion hæmolysis has a mortality greater than 50%. Treatment in the past has for the most part been empirical. Administration of alkalis, to prevent the blocking of tubules with acid hæmatin, has not proved of great value in preventing the onset of anuria, and decapsulation of one or both kidneys has not been generally accepted as a rational alternative to conservative treatment.

The case described here* is that of a soldier who appeared to be dying of extreme oliguria and uræmia following a massive hæmolysis after transfusion. Peters (1945) considered this condition to be the result of raised intrarenal tension, and summed up the position by stating that "both kidneys should be decapsulated as soon as the syndrome can be established by the presence of oliguria or anuria and azotæmia." Under the influence of this dogmatic statement one kidney was decapsulated —the other being left owing to the unique operative difficulties—and an immediate diuresis ensued with the eventual recovery of the patient. Urinary and blood findings were followed during the period of recovery.

A healthy, obese, thickset English soldier fell from a window in November, 1945, and sustained a fractured femur. After some ten weeks he was transferred to the orthopædic unit of a general hospital.

The femur was plated by Lieut.-Colonel W. Parke on the afternoon of Jan. 26. There was considerable hæmorrhage and 2 pints of group-O citrated blood, followed by glucose saline, was transfused while the patient was still under anæsthesia. His condition on return to the ward was poor; he vomited several times, was restless, and the pulse was rapid and of poor volume.

Early next morning he was shivering and febrile, and later conjunctival icterus was observed. Before midday he passed some 20 oz. of reddish urine containing blood pigment and some red cells. No further urine was passed on that day or the next, but, though fever continued, his general condition improved. Hæmolysis and anuria following transfusion was diagnosed. The hæmoglobin was 63% on the fourth day after operation, and differential agglutination revealed that more than 90% of transfused red cells had been hæmolysed. Both donors were regrouped and found to be group O, and direct matching with the recipient's serum showed no evidence of incompatibility. There had been no previous transfusions, and the only explanation of the hæmolysis seemed to be that the blood had been stored two weeks in a citrate anticoagulant solution not containing glucose.

Until decapsulation six days later there was almost complete anuria and a rising blood-urea level. On the second day no urine was obtained, and subsequently about 3 oz. was removed daily by catheterisation. The urine was at first faintly red and contained red cells; it gradually changed to brown and contained free bile, and later became amber. There was constantly a fairly heavy cloud of albumin, but no casts were seen.

Associated with anuria there was evidence of transient liver damage; the liver became enlarged and tender, jaundice developed, and the serum van den Bergh reaction was direct immediate positive. This appeared to have subsided by the sixth day.

The blood-urea level was already 225 mg. per 100 c.cm. on the third day after transfusion and thereafter continued to rise steeply. Fundal changes were absent and the blood-pressure was 150 mm. Hg systolic and 110–115 diastolic, remaining constant throughout his illness. The patient's general condition remained good; he felt comparatively well, his tongue was moist, and he was alert and talkative; there were no gastro-intestinal symptoms other than constipation, and his appetite remained excellent.

Medical treatment to induce diuresis was instituted as soon as hæmolysis was diagnosed. The daily fluid intake from all sources was restricted to about 1½ litres, and glucose saline with added alkalis and sodium sulphate was infused; these measures were without effect on the urine output.

On the sixth day, though there was little deterioration in the general condition, catheterisation again yielded barely 3 oz. of urine, and the blood-urea level had risen to 380 mg. per 100 c.cm. (see table I and figure). Decapsulation of the right kidney was performed under spinal anæsthesia by Lieut.-Colonel W. Parke.

The patient's physique and obesity and a waist-high spica plaster made delivery of the kidney almost impossible. It appeared normal in size but was dull purple, and on incision the capsule gaped, exposing the cortex, which was also dark purple and congested. Reflection of the capsule was easy, and each half was stripped over the upper and lower poles and pushed round to the hilum without being excised. The wound was closed, and, as oozing from muscles was free and difficult to control, a rubber drain was left in situ.

During the operation the patient appeared fairly comfortable. There was a fall in blood-pressure to 95/55 mm. Hg, presumably in part due to spinal anæsthesia, but pulse and general condition gave no cause for anxiety. He spent a fairly comfortable night, and next morning, though in some pain, appeared little affected by his operation.

Some fourteen hours after the patient's return from the theatre he passed urine voluntarily for the first time, and by the end of the first twenty-four hours 13½ oz. had been

High spinal anæsthesia given on evening of 15th day.
Fibrillation and heart-failure on evening of 18th day.

---

* The case was reported by Lieut.-Colonel W. Parke in a letter in THE LANCET, 1946, ii, 847.

passed. Diuresis was thereafter satisfactory and reached a maximum of 102 oz. in twenty-four hours on the ninth day, after which it gradually subsided.

The patient's general condition was not, however, immediately improved by the operation. Specific gravity of the urine remained at 1·010 for many days, and during the first four days after decapsulation the concentration of urea in the urine remained very little higher than that in the blood. The blood-urea level, though it ceased to increase so rapidly, continued to rise daily, and six days later 530 mg. per 100 c.cm. was recorded.

At this stage and for the next few days the clinical picture was complicated by an increasing anæmia as a result of oozing from the renal wound. A week after decapsulation, with sighing respiration, hiccough, a thickly coated tongue, and a return of conjunctival icterus, he was more seriously ill than at any time previously.

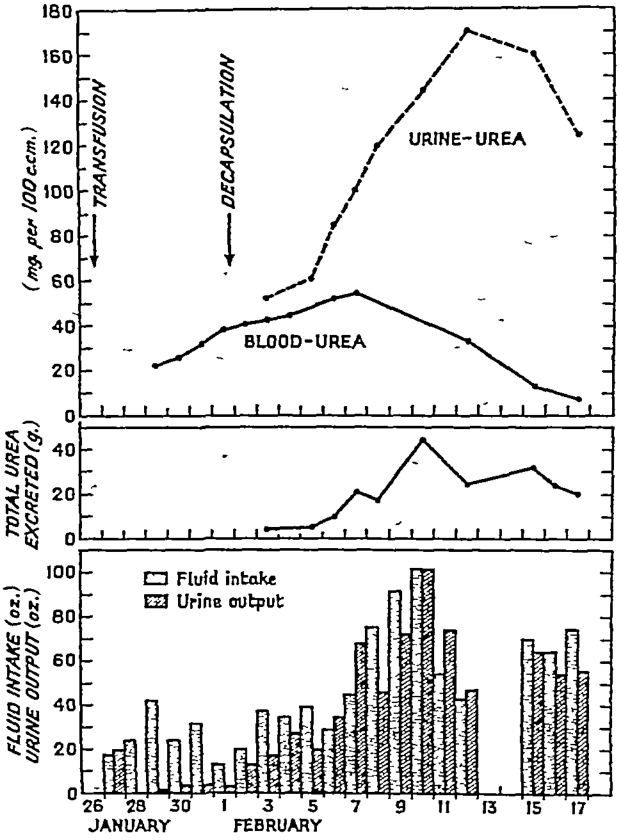
With a large urinary output, however, and as urine-urea concentration rose, the blood-urea level began to fall, and eventually did so as rapidly as it had risen. After a large transfusion with freshly drawn matched blood there was a further big improvement, and from this time on the patient made an uninterrupted recovery.

Ten days after decapsulation the blood-urea level had fallen to 320 mg. per 100 c.cm., and a week later to 70 mg. per 100 c.cm. On the twenty-third day after the initial operation, and seventeen days after decapsulation, he was repatriated to the U.K., thus making a final check on renal efficiency impossible.

The various findings during these twenty-three days, and including the fluid intake, urinary output, and urine-urea and blood-urea levels are shown in table I and the accompanying figure.

DISCUSSION

The patient had a severe intravascular hæmolysis following transfusion. Hæmolysis was followed by an almost complete anuria, and its usual sequel of progressive nitrogen retention but normal blood-pressure. Decapsulation of one kidney under spinal anæsthesia was followed by an immediate diuresis, which reached a maximum in ten days, and by a more gradual return to normal of urine and blood-urea level and by eventual recovery of the patient.



Fluid intake and output and urea findings.

TABLE III—RESULTS OF DECAPSULATION

Authors	Days after transfusion	Amount of urine before decapsulation (oz. daily)	Unilateral or bilateral	Amount of urine after decapsulation	Result
Bancroft (1925)	9	1–6	Bilateral	$9\frac{1}{2}$ oz. on 1st day, increasing daily to 50 oz. on 5th day	Good
Younge (1936)	5	2–3	Unilateral	8 oz. on 1st day; big excretion from wound for 5 days *	,,
Ravich (1941)	7	0–3	,,	12, 47, and 166 oz. in first 3 days	,,
Talbott (1942)	4	Anuria	,,	Flow established from both kidneys within 24 hours	,,
Flo and Cummings (1943)	9	2–3	,,	7, 20, and 10 oz. in first 3 days; incontinent 3rd day	,,

Present case	6	$0–3\frac{1}{2}$	,,	13, $17\frac{1}{2}$, and 28 oz. in first 3 days	Good

* This patient lost large quantities (about 1000 c.cm.) of fluid, "almost indistinguishable from urine," from the renal wound for five days after decapsulation.

The efficacy and the mode of action of decapsulation will be discussed later. If, for the moment, it is assumed that diuresis and recovery were not fortuitous but the results of the operation, the important issue is immediately raised of how soon after the establishment of anuria should operation be performed. Table I and the figure show that, though a satisfactory diuresis followed immediately, there was neither an immediate return of renal function, as shown by the urine-urea concentration, nor a rapid improvement in the uræmia, as judged by the clinical condition and the blood-urea level. The urine-urea level was, for several days, little higher than the blood-urea level, which rose from 380 to 530 mg. per 100 c.cm. by the sixth day after operation.

These findings in blood and urine were closely paralleled in a second case in which, after post-transfusion hæmolysis, twelve days' almost complete anuria terminated in spontaneous diuresis. The relevant data, summarised in table II, show that, four days after diuresis set in, the urine-urea concentration was still only 850 mg. per 100 c.cm., whereas the blood-urea level remained at 360–370 mg. per 100 c.cm., a concentration of only just over double, instead of about 50 to 100 times. This patient developed a toxic fibrillation and heart-failure, which led to a temporary check in the flow of urine, but, significantly, did not prevent a continued improvement in the concentrating power of the kidney.

It appears that, though diuresis was satisfactorily established, in one case apparently as the result of surgical interference and in the other spontaneously, the urine was, for a few days, little more than a glomerular filtrate undergoing little concentration in the tubules. This is not surprising. The products of hæmolysis are toxic, and as they pass down, and are concentrated in, the tubules they produce damage which, though reversible, is undoubtedly extensive. The findings suggest that tubular damage will not be repaired until anuria is relieved and the cellular debris, acid hæmatin, and other toxic products are washed away by the resulting diuresis. It follows that, if decapsulation or any other form of interference can be shown to be effective in producing diuresis, it should be done early—as soon as *anuria is established. Though diuresis may be immediate* and profuse, the concentrating power of the kidney recovers more slowly, and improvement in the patient's condition will be delayed for some days.

But is decapsulation effective? And if so, how does it initiate diuresis? The operation has, in the past, been used in the treatment of various anuric conditions. It is comparatively simple and of little danger to the patient compared with continued anuria. The whole subject was well reviewed by Abeshouse (1945), who held that it was effective in the anuria following mismatched transfusion. Despite considerable interest in the operation over a number of years, and much intensive study of the renal lesions in this and allied conditions during the war years, reported cases of anuria following transfusion treated either conservatively or by operation are curiously few. Of 46 patients treated conservatively, 31 (67%) died :

Authors	*No. of cases*	*No. of deaths*

Bordley (1931) (additional cases)	10	10
Daniels et al. (1941)	13	7
Goldring and Graef (1936)	7	3
Totals	46	31

Of 8 patients (including the present case) who underwent decapsulation 7 recovered (table III). Though the figures are too small for statistically significant conclusions to be drawn, they suggest that decapsulation does in some way lead to diuresis, and the impression is greatly strengthened by the uniform rapidity of its onset in every case, including the patient who died two days later.

Another significant point regarding the mode of action of decapsulation is that a good result appeared to follow operation on only one kidney in 7 of the 8 cases in table III. What little evidence is available suggests, moreover, that both kidneys recover their function though only one is decapsulated. After unilateral decapsulation for transfusion anuria, for instance, Lyons and Raines (1946) found normal phenolsulphonphthalein excretion (23% in half an hour from each kidney) twenty-six days later. Talbott (1942) performed unilateral decapsulation on the fourth day of oliguria and inserted ureteric catheters, collecting the urine from each kidney. There was good urinary flow, equal on the two sides, within twenty-four hours, and no striking difference in the renal efficiency on the two sides a fortnight later.

Talbott interpreted this result as implying that "unilateral decapsulation in this patient had no beneficial action on renal function." This does not necessarily follow, and the rapid recovery of renal function in both kidneys after one-sided decapsulation is a factor, were it established, that needs considering not only in explaining the good effects of the operation but also, by implication, in the elucidation of the ætiology of the anuria. Peters (1945) rejects plugging of the lumen of the tubules as sufficient explanation, and favours a mechanically raised intrarenal pressure produced by gross tubular damage and interstitial œdema. He demonstrates with an ingenious mechanical kidney that increased pressure, such as might be expected, will lead to a cessation of flow, and that lowering of tension to the extent that might be achieved by decapsulation can reinstate the flow, through his nephron. The theory is reasonable, and he naturally concludes that relief of intrarenal pressure by bilateral decapsulation will give the best results. Abeshouse (1945), on the other hand, discards tissue trauma, release of proteins from damaged muscles, drainage of subcapsular toxins, and other incidentals to operation, and considers, as do Lyons and Raines (1945), that removal of sympathetic tonic nerve-fibres reaching the kidney through the capsule, rather than relief of tension, is the most probable explanation *of the resulting diuresis.*

If the apparent success of decapsulation is due to removal of sympathetic tonic nerve impulses, is the resulting diuresis due, wholly or in part, not to the operation itself but to the high spinal anæsthesia usually employed; and would not spinal anæsthesia alone, or perhaps sympathetic nerve block, achieve the required result? The sympathetic nerves reach the kidney from the last two thoracic and first lumbar segments via the splanchnic nerves and the semilunar ganglion to the renal plexus. They influence renal secretion through their vasomotor action, stimulation producing diminished urinary output, and removal or paralysis causing polyuria. Neuwirt (1922) reported a case of reflex anuria due to very severe left-sided renal colic, in which bilateral splanchnic anæsthesia was followed by diuresis within a few hours. He considered this method preferable to spinal anæsthesia, because lowering of the blood-pressure was avoided. In the second case referred to in the present paper high spinal anæsthesia, induced on the day indicated in table II, was followed by an increase in urine from 59 to 101 oz. next day. Spontaneous diuresis was, however, already *in progress and could* well have been responsible for such a rise.

Peters (1942) appears to have described the first case in which splanchnic block was deliberately used in the treatment of anuria following hæmolysis. His patient, a Rh-negative subject, had complete anuria for ten days. Within five hours of bilateral block 700 c.cm. of urine was passed, and soon 1500–6000 c.cm. was being passed daily; recovery was complete. Since this article was written O'Sullivan and Spitzer (1946) have recorded a second case. Reporting a series of cases of acute renal failure complicating abortion, they describe two in which dramatic response followed bilateral splanchnic block. In one the anuria followed extensive hæmolysis after the last of several transfusions in a Rh-negative subject. In the second, a case of anuria complicating abortion, probably an essentially similar condition, in the treatment of which they consider decapsulation has no place, the patient also recovered, though only after a second splanchnic block done a few days after the first.

During the last few years it has become generally recognised that a similar pathology underlies the anuria developing in various conditions—e.g., crush syndrome, cortical necrosis in pregnancy and abortion, and sudden extensive intravascular hæmolysis from whatever cause. Recently evidence has been accumulating that in these conditions a redistribution of blood-flow within the kidney takes place, and that a closing down of the circulation through the cortex and its glomeruli gives rise to anuria, and, if sufficiently complete, cortical necrosis. This *condition of affairs Maegraith and Havard* (1946) have called renal anoxia. This conception has been vindicated by the important preliminary communication published by Trueta et al. (1946), wherein they claim that they have evidence, in animals, of the existence, via vasa recta and medullary blood channels, of an alternative route for blood passing through the kidney. They have demonstrated, radiologically and by direct inspection, a shunt of blood from the cortical to the medullary circulation as a result of various peripheral and central stimuli. They suggest that the lesion in "many loosely related syndromes—e.g., sulpha-kidney, incompatible transfusion kidney, Weil's disease, and some forms of nephritis—is the result of a defence device by which the cortex of the kidney is excluded from the circulating toxin or ther noxious agent, and thus protected. Too prolonged peration of this device may result in permanent lamage."

If this mechanism is under the control of the sympahetic nervous system, it is easy to see how the process nay be reversed by blocking the sympathetic. If this vere done soon after the onset of anuria, flow of blood hrough the glomeruli would be re-established, so preventing further cortical damage and also leading to liuresis and a more prompt elimination of toxic agents in he tubules. There is sufficient evidence to justify further rials of this comparatively trivial procedure in the reatment of all these allied types of anuria.

SUMMARY

A case of post-transfusion anuria is described in which lecapsulation was followed by immediate satisfactory liuresis and eventual recovery. Improvement in urea oncentration by the kidney and in the uræmic condition f the patient was delayed several days. Probably such mprovement cannot take place until diuresis sets in. t follows that, where decapsulation or other operative rocedure is contemplated, it should be undertaken arly.

The mortality in reported cases treated conservatively vas over 65%, whereas 7 of 8 patients recovered in whom lecapsulation was performed. Moreover diuresis invaribly followed within 12–24 hours, suggesting that coincilence is not an adequate explanation of their recovery.

Unilateral decapsulation appears to be sufficient and s probably followed by diuresis and eventual recovery n both kidneys.

Rapid diuresis but slow recovery of the concentrating ower of the kidney suggests that anuria and tubular lamage have a separate ætiology. Tubular damage is ustained as the toxic products of hæmolysis pass down nd are concentrated in the tubules. Raised intrarenal ension possibly plays its part in the production of anuria, ut a more satisfactory explanation is that it is reflex n origin, and that decapsulation is effective by removing ympathetic nerve impulses. Recent work has suggested ow such a reflex anuria may operate.

The spinal anæsthesia used in the operation of decapulation may be a factor in initiating diuresis.

Splanchnic block would be a more satisfactory method nd has been used with success in reflex anuria and in ransfusion kidney. The procedure is simple and deserves urther trial.

PALPABLE EPITROCHLEAR GLANDS

INCIDENCE AND RELATION TO SYPHILIS

LAURENCE MARTIN
M.D. Camb., M.R.C.P.
PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE

THE epitrochlear lymph-glands are seldom palpated as a routine in clinical examination but are more often sought for in special cases when their enlargement is expected. This practice has tended to establish a belief that all palpable epitrochlear glands are abnormal, because their normal limits of size and frequency of occurrence are not generally appreciated. There is, in particular, a common belief that their enlargement is suggestive of syphilis in the stage of general adenitis which precedes secondary skin eruptions. The origin of this sinister association, which still survives in some modern textbooks, is both ancient and dubious.

Richard Wiseman (1696) observed the epitrochlear glands in "King's evill" and believed that they were not "naturally born with us . . . but . . . arise upon the occasion of this disease," and their omission from writings of contemporary anatomists such as Salmon (1714) and Cheselden (1722) suggests that they were then unrecognised as normal structures.

Enlargement of the epitrochlear gland in primary syphilis when associated with a digital chancre aroused the curiosity of John Hunter (1810), who commented on one case in which epitrochlear adenitis had developed instead of an axillary bubo, and on another in which both epitrochlear and axillary glands were enlarged.

The belief that enlarged epitrochlear glands have a special diagnostic significance in syphilis at the pre-eruptive stage of adenitis is of obscure origin, and the literature contains conflicting opinions. Zeisler (1894) cited Sigmund as attaching particular significance to them at this stage, and Gruenfeld as having found them "without exception at certain periods of the disease." Hinton (1936) wrongly attributed to Fournier the opinion that enlarged epitrochlear glands were almost pathognomonic of tertiary syphilis. Fournier (1873) had, in fact, especially emphasised the rarity of their enlargement in the stage of general adenitis, insisted that their diagnostic significance had been grossly exaggerated, and fiercely reviled physicians who sought for non-existent glandular enlargement in the tertiary stage.

Lancereaux (1868) included the epitrochlear glands among those more rarely affected in the stage of general adenitis, whereas Ricord (1851) and Sir Jonathan Hutchinson (1909) did not mention them.

There is thus scanty support for a diagnostic significance of enlarged epitrochlear glands in syphilis from some of the greatest authorities, who in the pre-arsenical era probably saw more of the progressing disease than do most physicians living today.

PRESENT SURVEY

Palpable epitrochlear glands were so commonly observed in soldiers during the late war that I made a survey to define their normal limits of size and their incidence in adult males.

Of the 200 soldiers who were first examined, none had any disease which might cause a general adenitis or isolated enlargement of the epitrochlear glands. None were included who gave a history of "desert sores" on the hands or arms or who showed recent manual abrasions. Most had been referred for chest investigation, dyspepsia, fibrositis, sciatic pain, or urinary symptoms. It was not practicable to have a Wassermann reaction done in every case, but there was no evidence of syphilis in any.

The best method of detecting epitrochlear glands is to flex the patient's elbow to 90° and to palpate above the medial epicondyle of the humerus with a circular movement of the finger-tips. The glands can thus be rolled between the fingers and the lower end of the humeral shaft. It is more difficult to detect them in fat subjects than in thin.

TABLE I—EPITROCHLEAR GLANDS IN SOLDIERS

Age group (years)	No. of cases	Palpable glands			
		Bilateral	Right only	Left only	Total
16–20 ..	12	2	1	1	4 (33·3%)
21–25 ..	43	10	8	3	21 (48·8%)
26–30 ..	46	12	5	5	22 (47·8%)
31–35 ..	46	17	4	1	22 (47·8%)
36–40 ..	36	8	4	0	12 (33·3%)
41–45 ..	14	2	1	0	3 (21·4%)
46–50 ..	3	0	0	0	0 0
Total ..	200	51	23	10	84 (42·0%)

Table I shows that epitrochlear glands were palpable in 42% of 200 soldiers, with a remarkably constant frequency between the ages of twenty-one and thirty-five. In 17 cases one or both glands exceeded the size of a cherry-stone, and in 33 they were unilateral.

It seemed possible that some special factor in soldiers, such as repeated hand abrasions on the weapons and machinery of modern warfare, might have predisposed to minor infections and so increased the frequency with which epitrochlear glands were palpable. A control series of civilians not engaged in manual work would therefore have been desirable, but this presented obvious difficulties. Male civilians of military age were then in factory, agricultural, or transport work, which entailed equal opportunities of manual abrasions with military service, and few suitable hospital patients who were not so engaged were available. Nevertheless 100 civilian males, including hospital patients, healthy doctors, and laboratory-workers, were examined.

Table II shows that epitrochlear glands were palpable in 39% of 100 civilian males. In 3 cases they exceeded the size of cherry-stones, and in 16 they were unilateral.

TABLE II—EPITROCHLEAR GLANDS IN CIVILIANS

Age-group (years)	No. of cases	Palpable glands			
		Bilateral	Right only	Left only	Total
16–20 ..	10	3	0	1	4 (40·0%)
21–25 ..	13	4	1	1	6 (46·1%)
26–30 ..	16	3	2	1	6 (37·5%)
31–35 ..	19	6	4	3	13 (68·4%)
36–40 ..	15	2	0	1	3 (20·0%)
41–45 .	19	3	0	1	4 (21·0%)
46–50 ..	8	2	0	1	3 (37·5%)
Total ..	100	23	7	9	39 (39·0%)

There was no significant difference in their incidence between manual and non-manual workers.

It seems, then, that epitrochlear glands are palpable in about 40% of males between the ages of sixteen and fifty, whether soldiers or civilians. In the combined series of 200 soldiers and 100 civilians 197 epitrochlear glands were palpable, of which 28 (14·2%) exceeded the size of a cherry-stone. These findings indicate the need for caution in declaring a palpable epitrochlear gland to be abnormal or enlarged.

It is not denied that enlarged epitrochlear glands may be part of a syphilitic adenitis, but there is no reason for attaching a diagnostic significance to them, for they are often enlarged in other adenopathies, such as those of leukæmia, glandular fever, Hodgkin's disease, and tuberculosis. The present survey suggests that no epitrochlear gland smaller than a cherry-stone can safely be regarded as abnormal. Apart from the criterion of size, other factors, such as tenderness, the degree of mobility, and consistence of the gland, must be taken into account before describing palpability or enlargement as pathological.

SUMMARY

A survey comprising 200 soldiers and 100 male civilians between the ages of sixteen and fifty showed that epitrochlear glands were palpable in about 40%.

Of the palpable epitrochlear glands, 14% exceeded the size of a cherry-stone.

Appreciation of these normal limits is essential before describing a palpable epitrochlear gland as enlarged or pathological.

There is no reliable evidence to support the belief that enlarged epitrochlear glands are more characteristic of syphilis than of other diseases which cause glandular enlargement.

REVACCINATION IN ADULTS

J. C. Broom
M.D. St. And.

From the Wellcome Laboratories of Tropical Medicine, London

During 1945 civilians were recruited by Unrra to administer the camps then being set up in North-Western Europe for "displaced persons." On the assumption that the risk of infection would be high in these camps it was decided that every member of the staffs should be vaccinated against smallpox unless he, or she, possessed a certificate of vaccination less than a year old.

The result of the vaccination performed by us, and the length of time which had elapsed since previous vaccination, were recorded. The following notes are based on 1364 vaccinations for which complete records are available. All vaccinations and readings of results were carried out by one person under conditions standardised from experience gained during a series of 400–500 vaccinations not included in this report.

MATERIALS AND METHODS

The subjects were adults of all ages between 20 and 60 years. Records of age were not made, but the numbers were fairly evenly distributed among the different age-groups. The sexes also were about equally represented.

The histories of earlier vaccinations varied greatly: many of those with long residence abroad or service in the Armed Forces claimed to have been vaccinated on numerous occasions; nearly half had not been vaccinated since infancy; and about 10% had never been vaccinated.

Lymph was obtained in ampoules containing 25 or 50 doses fresh each week from the Government Lymph Establishment. Part of each batch was stored at 4° C until required; the remainder was heated at 65° C for 30 min. to destroy the virus and was used as a control for protein sensitivity. The first few batches of heated lymph were tested by intradermal inoculation into rabbits to ensure that the virus had been killed; later, the fact that normal lymph "took" in susceptible persons, whereas the heated did not, was accepted as proof of inactivation of the virus.

The heated and unheated lymphs were of the same batch at any one session, but many different batches were used throughout the whole series of vaccinations.

Technique of Vaccination.—The average number of persons vaccinated at one session was 40–50. The left arm was the site of election, but a few females insisted on vaccination on the thigh. The deltoid region was cleaned by gentle swabbing with a mixture of ether and methylated spirit, and dried with cotton-wool. One drop of heated and one drop of active lymph were placed some 2 in. apart on the cleaned area. An incision about $^1/_4$ in. long was made through the heated lymph with a scalpel, and the material was rubbed into the cut with the flat of the knife; with the same scalpel, the process was repeated with the active lymph. The arm was left bare until the lymph had dried. No dressing was applied.

Reading of Results.—Each vaccination was observed after 2 or 3 days and again on the 8th day. Reactions were graded according to the time taken for the maximum to be reached, no account being taken of relative severity. This follows the line suggested by Leake,[1] though it was not possible to make daily measurements of the area of erythema which his complete method involves.

The following types of reaction are recognised by the International Sanitary Convention, 1944:

Typical Primary Vaccinia.—Maximum between 8th and 12th days, indicates complete susceptibility.

Accelerated Reaction (vaccinoid).—Maximum between 4th and 7th days, indicates partial residual immunity.

Reaction of Immunity.—Maximum between 2nd and 3rd days, indicates complete residual immunity.

A positive control reaction was recorded when, at the site of insertion of heated lymph, the skin incision showed gaping edges and was surrounded by an area of erythema about 5 mm. or more in diameter. In the non-susceptible individual no erythema was normally visible and the incision was obviously healing.

A second vaccination was done on the 8th day in all cases showing "no reaction." Thereafter most of these patients were seen on a single further occasion only (3 days later), because they were posted overseas. The readings of the second vaccinations were therefore tentative and not final.

RESULTS OF REVACCINATION WITH CALF LYMPH AT VARIOUS INTERVALS AFTER PREVIOUS VACCINATION

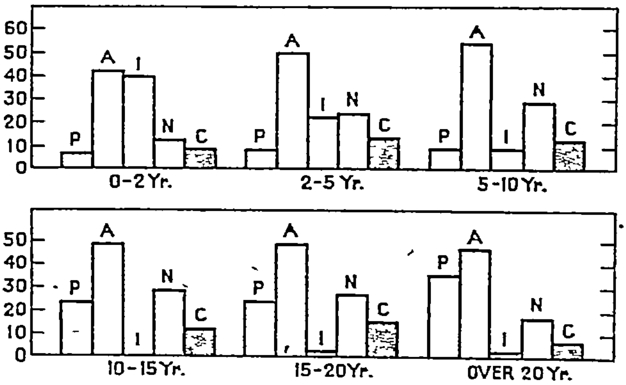
Years since last vaccination	Results					
	Primary	Accelerated	Immune	Nil	Total	Control reactions
0– 2	9	67	64	20	160	14
2– 5	15	97	40	43	195	25
5–10	8	48	8	25	89	10
10–15	16	34	0	20	70	8
15–20	25	54	3	30	112	16
> 20	213	284	4	100	601	37
Total ..	286	584	119	238	1227	110
Primary vaccinations	135	2	0	0	137	—

RESULTS

The results of these vaccinations are set out in the accompanying table, grouped according to the length of time which had elapsed since previous vaccination. In the accompanying figure the total in each group has been taken as 100 to facilitate comparison.

It will be seen that "control" reactions occur in all groups, and that the chance of such a reaction remains high for at least 20 years after vaccination. The relative number of primary vaccinias rises, and of immune reactions falls, with increase of the time interval. On the other hand, the proportion of accelerated reactions lies between 40% and 50% at all periods.

The table also includes the results obtained in 137 adults vaccinated for the first time. All these vaccinations "took" successfully. They formed a useful check on the technique and on the potency of the lymph because, by chance, two or more of these primary vaccinations were carried out at each session.



Percentage distribution of results of revaccination after various intervals: P, primary vaccinia; A, accelerated reaction; I, reaction of immunity; N, no result; C, positive reaction with heated lymph.

The results of second vaccinations are not shown because, as stated above, no final reading was made. It may be said, however, that of 201 second vaccinations 39 (20%) were considered as probable accelerated reactions when examined on the 3rd day, and the remaining 80% as again negative. It has been our experience that the beginning of an accelerated reaction can almost invariably be distinguished on the 3rd day; so these proportions are in all likelihood reasonably correct.

DISCUSSION

For practical purposes the occurrence of either an accelerated reaction or a primary vaccinia means that the vaccination has been "successful," but the differentiation into two types is of academic and epidemiological interest on the assumption that the former indicates partial immunity retained from previous vaccination and the latter shows complete susceptibility. In our experience the distinction can be made with confidence on the 8th day; an accelerated reaction is then obviously past the maximum and is beginning to form an eschar, whereas a primary vaccinia is just reaching the stage of pustulation.

The reaction of immunity, as a sign of complete protection resulting from previous vaccination, would be of great value if it could be recognised with certainty. This can be done when a papule surrounded by an area of erythema appears at the site of insertion of active lymph, and no reaction at all is caused by the heated material; such a result can be accepted as an immune reaction. Doubt must arise, however, when some reaction, though less in degree than that caused by the active lymph, is produced by heated lymph. It seems impossible to assess these cases by an objective standard, and it was our custom to take the past history into account. If the previous vaccination had been within 5 years and had left an obvious scar, the result was recorded as an immune reaction. After a longer interval, or if no scar was apparent, and in all cases of doubt, a second vaccination was performed. It is probable that this method erred on the side of safety because, as noted above, 80% of cases classed as "nil" on first vaccination showed no greater reaction 3 days after the second attempt.

---

1. Leake, J. P. *Publ. Hlth Rep., Wash.* 1927, 42, 221.

The occurrence of about 5% of primary vaccinias in persons last vaccinated within 2 years was unexpected. Since, however, no scar related to that "vaccination" was ever observed, it seems likely that a non-specific reaction had been mistaken for a reaction of immunity. This was certainly the explanation in the case of a nurse who had been vaccinated, for the first time since infancy, a few months earlier, and had been certified immune. Feeling that the result was unlikely, she requested revaccination. After 3 days there was marked erythema round both active and heated lymph insertions, but a typical primary vaccinia developed later. This case also illustrates the lack of correlation between immunity and sensitivity to vaccine products, to which attention has often been drawn before.

The value of the immune reaction can thus be questioned for two reasons. First, the existence of persons who, without being immune to living virus, react to heated lymph in a manner which may closely simulate the reaction of immunity and may lead to mistaken readings. Secondly, the existence of others who are immune to vaccinia virus on the evidence of lack of response to repeated vaccinations but do not show a reaction of immunity.

There are grounds, therefore, for suggesting that some alteration in the international certificate of vaccination against smallpox would be advisable, because therein the reaction of immunity is accepted as valid, whereas no provision is made for lack of susceptibility—indeed it is stated "A certificate of no reaction will not be accepted." The method adopted by the British Army seems to offer a good alternative: the first vaccination is made by a single insertion and is examined a week later, no earlier observation being made. If a satisfactory "take" has not occurred, revaccination is carried out with three insertions; if again no reaction is obtained, "insusceptibility to vaccination" is recorded, and this certificate is valid for the same period as one of successful vaccination of the same date.

SUMMARY

A series of 1227 adult revaccinations against smallpox is described.

Details are given of the method of vaccination, including the insertion of killed virus as an indicator of sensitivity to vaccine lymph.

The results are grouped according to the type of response and the length of time since previous vaccination.

Sensitivity reactions are shown to develop at all intervals and to be unrelated to immunity.

It is suggested that these reactions lead on occasion to misinterpretation of the response to vaccination.

Attention is drawn to the lack of provision, in the international certificate of vaccination against smallpox, of a category to include persons who are insusceptible to vaccinia but do not show the reaction of immunity; an alternative method of certification is proposed.

"Some . . . benefit by taking only one meal a day . . . while others . . . make it a rule to take lunch as well as dinner. . . . For the one class, if they lunch though to do so is not beneficial to them, are at once heavy and sluggish in body and mind, being overcome with yawning, drowsiness and thirst, and if they go on to take dinner as well, they suffer from flatulence and colic, with violent diarrhœa. . . . On the other hand, if a man in the habit of taking lunch . . . refrain from doing so, he experiences at once . . . severe prostration, trembling and faintness. In addition, the eyes become hollow, the urine yellower and hotter, the mouth bitter, his bowels seeming to hang, with dizziness, depression and disinclination to exertion. Besides all this, when he tries to take dinner . . . this mere food, descending into the belly with colic and noise, burns it up; the patients sleep badly, with disturbed and troubled dreams."—From *Ancient Medicine* (ANON. ? 430–400 B.C.), translated by W. H. S. JONES (*Bull. Hist. Med.* suppl. no. 8: Philosophy and Medicine in Ancient Greece).

SEXUAL INVERSION

AN ETHICAL STUDY

D. STANLEY-JONES
M.B., B.Sc. Lond., F.R.C.S.

SEXUAL inversion is an attitude of mind in which the affections are turned toward members of the same sex. It is also called homosexuality (from the Greek *homos*, "same," as distinct from *heteros*, "other"; it is in no way connected with the Latin *homo*, "man"), and is properly considered only in relation to heterosexuality, in which the affections are turned towards members of the opposite sex.

Homosexuality does not necessarily imply any overt manifestation of physical sex. Lack of recognition of this fact is but one of many misconceptions that obscure clear thinking on this topic; there are many thousands of adults whose conduct is beyond reproach and who are useful and valuable members of their community, but whose interests lie exclusively with those of their own sex, and who with every propriety in the use of the word may be termed homosexual. The word itself bears, or should bear, no stigma of shame.

Heterosexuality also implies no connotation of physical sex, and may be correctly used to indicate a mixed group of males and females, such as a co-educational school, which is a heterosexual group, whereas the conventional public school may be described as a homosexual group. Popular prejudice, however, makes it unwise to use these terms in this way. As with a group, so also with the range of individual affections: the love of a mother for her son, of a brother for his sister, of husband and wife, are examples of heterosexual attitudes, whereas friendships between man and man, pupil and teacher, father and son, are all well-recognised types of homosexuality.

EVOLUTION OF AFFECTIONS

The growing child stands in an ambivalent attitude towards his parents, in which there are not only rapid alternations of love and hate, of laughter and tears, but also the closely interwoven strands of heterosexual and homosexual love, twin motifs which blend themselves into the pattern of subsequent love relationships. It is necessary to trace the normal course of both these strands as they change with the growing years.

The infant boy directs his affection toward the mother who feeds and tends him, and for the first five or six years his orientation is predominantly heterosexual. Sooner or later, however, there comes a change, and father comes into notice, at first merely as a source of supply and security, an ever present background to the little world of the nursery, but later in a more personal way as a friend and, if the home is happy, as a hero.

As the boy's interests spread, he chooses his heroes from other boys' fathers, from his school-teacher, his club-leader, or his scoutmaster, of whom unwittingly he makes father-substitutes; later his hierarchy is recruited from those nearer his own age, the athletes and elder boys of his circle, and the process reaches its climax in the period aptly termed by Furfey[1] "the gang age" of small-boydom, which is familiar to all parents who have watched their son pass through this trying stage. Mother, nurse, and sister have no place among the gods of the pre-adolescent, the group is all-in-all, and feminine influence disappears from his life: it is necessary that this should be so.

The attitude of this phase is exclusively homosexual; but, as the first age of friendship typically occupies the years of pre-adolescence, sexual manifestations on a physical or genital level are the exception, though some harmless sadism (which is not without its deeper significance) is not infrequent.

---

[1] Furfey, P. H. The Gang Age. New York, 1926.

The break-up of the gang is brought about by the onset of puberty, which ushers in the critical period. Feminine influence demands readmission after its long exile, and from now onwards heterosexual development takes its normal course, starting with the first shy and clumsy calf-love, till the full circle of the generations enters its final phase. The boy, now approaching manhood, takes up a protective attitude toward a mate of the same sex as his mother who first gave protection to him. There has been brought about a complete reversal of heterosexual relationship, from the attitude of infantile dependence, taking all and giving nothing, to that of protective love.

This reversal of the stream of affection from the self to another is rendered possible only by the disappearance of the mother, and all who resemble her, during the long latent period between childhood and puberty. The homosexual phase, therefore, and the homosexual attitude, far from being a malign perversion of all that is natural, is no less essential than heterosexuality itself in the development of the adult personality.

THE CRITICAL STAGE

At the critical stage of passing from homosexuality to heterosexuality there commonly occurs a transient phenomenon in which a pure affection may be aroused by a younger boy, and not infrequently a real friendship may develop. To the elder partner in this romantic attachment there is afforded a most helpful link in the transition from group loyalty to heterosexual love, and he is given an opportunity to exercise on familiar ground the sense of protection and chivalry which soon must play an important part in his approach to the other sex, to which he is as yet a stranger. The youth is fortunate in his friendships who can pass smoothly from a girl-like boy to a boy-like girl during this decisive phase.

In some cases, however, this smooth passage is interrupted. If the circumstances of the boyish friendship are such as to invest it with an unusual degree of pleasure, if the elder boy has been starved of his normal quota of respect which is his due, or if his vanity has been fed by unwise influences at home, he may find that the element of hero-worship which characterises this type of companionship is so much to his liking that he is content to remain here. If, moreover, there are obstacles in the way of his further progress, such as a degree of adolescent gaucherie or a sense of inferiority which cripples his relations with girls of his own age and class, a deeply rooted fixation will arise at the level of homosexual friendship.

Undoubtedly the commonest cause of emotional blockage at this stage is the public-school system of education, in which boys are thrown together in circumstances that necessitate an artificial prolongation of the homosexual group of earlier years, which in a more natural environment should have suffered disintegration at or before the time when the impulses of physical desire make their appearance. The group is maintained in a condition of metastable equilibrium, and the spirit of the gang crystallises as loyalties which by their unreasoning intensity betray their complexive origin. But these youthful deviations are corrected with the onset of maturity, and there is no doubt that the capacity for leadership, and in particular for leadership of men, together with the sense of loyalty which characterise the British race are directly attributable to the boarding-school type of education which is so typical of this country. Sublimated homosexuality plays an immensely important part in the structure of society both at home and abroad, in every way comparable to the rôle of heterosexuality, which, as the foundation of family life, is acknowledged as the basis of our social system.

There remains, however, the problem of the individual who does not conform to type, and in whom the element of sexual desire has arisen to complicate his already grave psychological difficulties. Not infrequently it is the superior type of boy, who in the best sense of the word is an "individual," who finds himself unable to adapt himself to an unwonted distortion of emotional development. The endocrine system compels the inexorable changes of body and mind, and rather than stoop to masturbation—that most unnatural of vices because so entirely the product of an artificial civilisation[2]—the boy injects his adolescent ideals of physical beauty into the romantic friendship of the moment, and fixation at this level persists into the years of manhood. In less abnormal circumstances he would have withdrawn from the homosexual gang with the onset of puberty, and entered the age of romantic friendship before the appearance of physical desire, whose resurgence should coincide with the renewal of contacts with the opposite sex which furnish his natural phantasies with their material. If a youth is starved of this essential stimulus to sexual growth he will remain throughout his adult life at the sexual orientation of pre-adolescence, though having attained the bodily stature of maturity. The principal factor, therefore, in the onset of this condition is an external maladjustment of timing, operating on a fundamentally normal personality at a most critical phase of its development; there is no question, in the majority of cases of homosexuality, of endocrine dysfunction, the "female soul in a male body," still less of any streak of moral delinquency or inborn vice.

MEDICO-LEGAL ASPECTS

The clinical aspect of homosexuality which is most likely to obtrude itself on the notice of the general practitioner is in connexion with an alleged seduction of a young boy by a male invert. In many cases it is to the family doctor in the first instance that the harassed parents turn for advice, before taking the irrevocable step of reporting their suspicions to the police. There immediately arises a grave problem of responsibility, and it is no light matter to decide in which way a doctor may best discharge his duty when confronted with an issue of this nature. There is an acute dilemma at the highest ethical level.

It cannot be denied that the profession has obligations to society at large as well as to individual patients, but the controversy over the proposed State medical service has indicated in no equivocal manner that most doctors consider that their duty to the State is discharged most usefully through their duty to their patients who collectively form the State, rather than to a suprapersonal entity or abstraction to which individuality, their own no less than their patients', is subordinated.

Every doctor is entitled to act on the judgment of his own conscience, and in a matter such as this there can be no doubt that the first (but not the only) consideration is the welfare of the young boy who has been seduced, and whose best interests the family doctor has been called in to protect. This burden cannot wisely be discharged by passing it on to an unimaginative and uninstructed inspector, whose outlook has been conditioned by the conspiracy of silence for which the profession as a whole must take a major share of the blame. Such a step would inflict grave injury on the boy in question, who would perforce be subjected to the most sordid interrogation, and then be enmeshed in all the paraphernalia of criminal litigation. It would be along the path of least resistance, but also of least benefit to everyone concerned, least of all to the unfortunate boy whose interests the family doctor holds in trust as the one person who is in a position to give enlightened advice.

The emotional trauma suffered in the first instance by a boy who has been involved in a homosexual friendship is minimal, even when it is complicated by manifestations of physical sex.[3] Thousands of young boys at boarding school every year make some acquaintance with the problem, and among boys from other strata of society mutual masturbation and other sexual peccadilloes are of frequent occurrence during the years of puberty; they have in fact until quite recently formed one of the main channels—albeit undesirable—of sexual education among the masses. No attempt at exculpation is to be interpolated into these remarks, but a sense of proportion is necessary here.

---

[2] Stanley Jones, D. *Brit. med. J.* 1940, ii, 206.

By far the most important factor touching the boy's inner psychology is completely and invariably overlooked—namely, that he has allowed himself, probably against his wishes, to be drawn into homosexual practices solely because of his attitude of hero-worship toward the man who has led him astray. His ideals in this respect are at far greater hazard to suffer damage than the natural course of his sexual growth, which has behind it the irresistible urge of the endocrine glands to restore him to the path of normality. His concept of manhood should descend in unbroken line through his successive father-substitutes, and for better or for worse it will have decisive influence not only on the tone of every detail of his adult behaviour but also on his whole approach to the wider issue of fatherhood. It is difficult to imagine a more certain way of inflicting irreparable damage on adolescent ideals than to drag through the mud of the magistrates' court, and later of the assizes, the unwholesome details of an intense friendship with which these ideals were inextricably bound, and which, however undesirable in the physical plane, was (unless the boy was utterly depraved) almost certainly not without another and less unpleasing side.

This aspect of sexual inversion may be unfamiliar to some; but, far from being revolutionary, it is merely a return to the commonplace beliefs of classical Greece, which in the opinion of many scholars contributed not a little to her greatness. This point of view was ultimately displaced by the Hebrew traditions of sexual severity that inform the patterns of morality in our western world.[4] The following quotation is from a book published in 1896 and now in its nineteenth edition[5]:

> "Personal affection was not the basis of married life; romance took a different form, that of passionate friendships between men. Such friendships among the Greeks were an institution. Their ideal was the development and education of the younger by the older man, and they were recognised and approved by custom and law as an important factor in the state.
>
> "In Sparta, for example, it was the rule that every boy had attached to him some elder youth by whom he was constantly attended, admonished, and trained. The celebrated 'Theban band,' consisting exclusively of pairs of lovers, marched and fought in battle side by side, and by their presence and example inspired one another to a courage so constant and high that 'it is stated that they were never beaten until the battle of Chæronea, and when Philip, after the fight, came to the place where the three hundred lay dead together, he wondered, and understanding that it was the band of lovers, he shed tears.' (*Plutarch*, *Pelopidas*, chap. 18.)
>
> "Greek legend and history resound with the praises of friends, names that recall at once all that is most romantic in the passion of Greece. Not only, nor primarily, the physical sense was touched, but mainly and in chief the imagination and intellect. The affection of Achilles for Patroclus is as intense as that of a lover for his mistress (*Iliad* XXIV). It was his insistence on friendship as an incentive to a noble life that was the secret of the power of Socrates.
>
> "So much indeed were the Greeks impressed with the manliness of this passion, with its power to prompt to high thought and heroic action, that some of the best of them set the love of man for man above that of man for woman. It is in the works of Plato that this view is most completely and exquisitely set forth; among all the forms of love, that one is chief which is conceived by one man for another. Such a love is the initiation into the higher life, the spring at once of virtue, of philosophy, and of religion.
>
> "That there was another side to the matter goes without saying. This passion, like any other, has its depths as well as its heights. Still the fact remains that it was friendship that supplied to the Greeks that element of romance which plays so large a part in modern life; and it is to this, and not to the relations between men and women, that we must look for the highest reaches of their emotional experience."

Two thousand years of heterosexual civilisation have intervened since then, and the Greek view of life is unlikely to commend itself to the average general practitioner or to the anxious parents who have come to him for help. The immediate pressure of circumstances moulds our opinions and forms our beliefs, besides dictating our actions, but an enlightened view of the habits of other times is the mark of the man of culture. A widely sympathetic approach to the difficulties of the problem may serve to keep under control a situation which in less cautious hands would inevitably progress into a major tragedy. The family doctor who is resolute in his endeavour to protect the interests of the injured boy will see that so far as possible his young patient is spared the horror of having to give detailed evidence in criminal proceedings; his decision to advise the parents on these lines will be greatly fortified by a familiarity with ways of thinking that derive from other days.

THE DOCTOR'S RESPONSIBILITY

The general practitioner's responsibility as regards the offender also demands consideration. To counsel the parents to seek police intervention in no way discharges that responsibility, but merely passes on the burden to others who are less fitted to bear it, besides implicating in unsavoury proceedings the very patient whom he is seeking to protect. Should he be tempted to delude himself into thinking that it is to the invert's ultimate advantage to be kept in protective custody while undergoing treatment for his abnormality, and that the prison authorities will study the patient's convenience to the extent of sending him to the particular gaol (if any) where such treatment is available, he would do well to reflect that a major factor in the causation of homosexuality is a fixation at the point of transition to heterosexuality, and that, no matter how skilled the physician, his best work is wasted without a change of circumstance which will facilitate the development of heterosexual friendships. To commit a cultured invert to the soul-crushing durance of a long term of penal servitude, where his only contact with the opposite sex is an occasional sight of the prison charwoman, is as futile from the point of view of treatment as to hope to rehabilitate a chronic alcoholic by giving him occupational therapy in a brewery.[6]

To enter into the technicalities of treatment of sexual inversion is no part of the purpose of this article; rather is it to indicate in a simple manner those aspects of homosexuality which are most likely to come to the notice of the family doctor, and to suggest how best he may reconcile the conflict of loyalties, the conflict between the State and the two patients with whom he is directly concerned. For there can be no doubt that contact must be made with the elder boy or man who is the offender, and that this contact can be only on a professional basis, which at once and automatically establishes the doctor-patient relationship: the guilty person can face the doctor only as a healer and not as a judge, and he as a patient is entitled to the fullest benefit of the seal of professional secrecy.

[6] Stanley-Jones, D. *Brit. med. J.* 1946, i, 179.

There is, further, the burden of moral responsibility occasioned by mere juxtaposition of circumstance, which is clearly recognised in the case, say, of a traffic accident, and this also lays upon the doctor who is concerned with the incident the duty of getting into touch with the offender, if necessary on his own initiative, and of helping him in a need which is a thousandfold greater than that of the injured party.

Sufficient has been said to indicate that this burden cannot be laid aside by taking the easiest way out of an unpleasant situation ; not only does police intervention effectively and finally bar the way to any possibility of cure, but also it is difficult to see how a moral duty to society can be discharged by causing irreparable injury to one of its members, unless one is prepared to defend the ethical position that the greater good justifies the lesser evil. In which case the hypothetical greater good, after being defined, must establish its claim to certainty without a reasonable doubt, and in the present instance this is far from being so.

In the final analysis the problem resolves itself into a special case of the question of professional secrecy, and a return to first principles would indicate that, when a doctor is entrusted with a secret of guilt, he must be assured that the welfare of the future is sufficiently safeguarded, but he is under no obligation to satisfy the claims (other than to due recompense) of the irrevocable past. He must use his utmost endeavours to guard against a recurrence of the offence, but even here he should duly weigh the very problematical risk of further damage to boys in the patient's neighbourhood against the certainty of utter damnation if the law is allowed to exact its merciless and unfeeling penalty. There may be indications for the therapy of fear, albeit tempered with wisdom, and the wise doctor will ensure that the elder patient places himself unreservedly in the hands of a competent psychotherapist and remains there until the possibility of a relapse has passed. It is unlikely, however, that any suggestion of threat or coercion will be necessary, since the type of invert whose compulsions lead him into criminal offences with younger persons has acute insight into his unhappy condition, and is ever willing to grasp the hand of any who will stretch out to save him.

In the case of the irreclaimable offender (whose moral responsibility may be likened to that of a known typhoid carrier), undoubtedly the only satisfactory solution lies in a permanent segregation under humane conditions of the type aimed at in the " treatment " of incurable insanity. This, however, is at present a counsel of perfection. The burden of this essay is that it is the medical profession collectively that is responsible, by its policy of silence, for the present lack of facilities for the treatment of sexual psychopaths, and therefore it is the moral duty of medical practitioners individually to shoulder in the first place the heavy responsibility of dealing with cases of this nature. To the conflict between the claims of the community and the needs of the individual there can be, in this as in many other issues, no finality. The line of thought here suggested is but one out of several possible avenues of approach.

" The limited tenure of research positions under short-term grants is precarious and injurious for the investigator in training or pursuing a career. The determination and direction of fields of research by the distant control, often from beyond the grave, of available funds is inhibitory and stultifying to those who prefer to follow freely the bent of their own curiosity. In some instances a foundation has sought to remedy the situation by granting ' fluid ' research funds to certain medical schools to be administered by the faculty of the school itself. Wherever this has been tried I believe it has been eminently successful."—DR. ERNEST W. GOODPASTURE, *Science*, 1946, **104**, 473.

ANTERIOR BONE GRAFT FOR RECURRENT SHOULDER DISLOCATION

J. C. R. HINDENACH
M.D. N.Z., F.R.C.S.

ORTHOPÆDIC SURGEON, WEST LONDON HOSPITAL; ORTHOPÆDIC CHIEF ASSISTANT, ST. GEORGE'S HOSPITAL

THERE are already many different operations for recurrent dislocation of the shoulder, and this is not an attempt to introduce a new one. My aim is to call attention to an operation which is popular in Sweden and the United States and has a definite application in some difficult cases.

Treatment by anterior bone graft was first instituted by Eden in 1917. It is comparable with Putti's shelf operation for congenital dislocation of the shoulder, corrects the lesion at the appropriate site, and is fairly easy.

The *pathology of recurrent anterior dislocation* of the shoulder has been well recognised since Bankart's (1938) paper, and its amplification by Hill and Sachs (1940), Eyre-Brook (1942), and Bost and Inman (1942). The salient points are :

(1) Primary trauma which drives the head directly forwards.

(2) Injury to the labrum glenoidale, which, with the anterior capsule, is torn from the glenoid margin.

(3) Failure of the labrum glenoidale to become reattached to the glenoid rim, with resulting lack of restraint to the forward passage of the humeral head.

(4) A compression fracture of the posterolateral portion of the humeral head, caused by a digging-in action of the anterior glenoid rim during dislocation. This is a late phenomenon, present in old recurrent cases and demonstrable by radiograms of the shoulder taken with the arm in full internal rotation.

(5) Secondary changes, with traumatic arthritis, proliferation of bone at the scapular and humeral necks, eburnation of the glenoid rim, production of loose bodies, synovial thickening, and cartilaginous degeneration of the humeral head.

The *operations for preventing recurrence* have been aimed at various structures in the joint : capsule and ligaments (Bankart 1938) ; tendons and muscles (Nicola 1929) ; and bony structures (Eden 1920).

Bankart's operation, by which the torn edge of the capsule is reattached to the glenoid margin, has certain disadvantages : the boring of the drill holes is difficult, even with a dentist's angled drill, and the holes tend to cut out ; the articular cartilage of the glenoid fossa is damaged by the drilling ; an old fracture of the anterior rim may complicate the procedure ; and the capsule may be thin and unsuitable for suturing.

Repair by bone block is simple and effective.

Eden (1920) inserted a tibial graft under the periosteum of the scapular neck, allowing it to project 10 mm. beyond the glenoid rim.

Hybbinette, as reported by Orell (1940), used first a tibial graft in 1917, and later an iliac graft.

Oudard (1924) displaced a graft from the coracoid process to the anterior glenoid rim.

Speed (1927) placed a tibial graft extracapsularly on the anterior scapular neck in three cases.

Orell (1940) made a cleft extracapsularly in the scapular neck with a special osteoperforator and inserted a pointed os-purum transplant. Owing to rapid new bone formation immobilisation of the arm was necessary for only fourteen days.

A combined procedure of an anterior iliac graft and a Nicola tenosuspension was described by Ilfeld and Holder (1943).

All the above have reported good results with no recurrence and with full range and power in the arm.

OPERATION

The anterior iliac graft operation is simple, the removal of the graft from the ilium taking little more time than the tedious drilling and threading of the holes in the glenoid rim required by Bankart's operation. The technique is as follows :

(1) The joint is approached through a longitudinal incision separating the deltoid and pectoralis major muscles.

(2) The tip of the coracoid process, with its attachments of pectoralis minor, coracobrachialis, and short head of biceps, is cut across with bone forceps and turned down.

(3) The anterior circumflex vessels are isolated and divided between ligatures.

(4) The subscapularis muscle is exposed, cut across near its insertion, and reflected medially to expose the capsule. The division should not be too lateral, as the blending of the tendon with the capsule renders separation difficult.

(5) The capsule may then be found attached to a free *labrum glenoidale* and, on pulling the latter laterally, the joint and humeral head are exposed. Sometimes, owing to scarring, the capsule may have to be incised close and parallel to the glenoid rim to expose the detached labrum and the bare anterior border of the glenoid fossa which communicates directly without hindrance with the anterior neck of the scapula.

(6) A vertical incision is made in the periosteum of the scapular neck about $^1/_2$ in. from the glenoid margin. With a 1-in. osteotome a bone flap is easily raised in the cancellous tissue of the neck, and the bone is also rawed between this incision and the glenoid rim.

(7) The anterior part of the crest and outer surface of the ilium is exposed subperiosteally, and a bone graft 1 in. by $2^1/_2$ in. is excised. The graft should consist of half the thickness of the crest and the outer cortex. The curve on this graft is eminently suitable for its close fitting to the hollow of the scapular neck. The graft is inserted under the scapular bone flap so as to project about $^1/_3$ in. beyond the glenoid margin and lie extracapsularly. If the approach allows, the graft may be fixed in position with a vitallium screw.

(8) The cut subscapularis muscle is sutured over the graft and holds it firmly in position. The coracoid is replaced and retained in position with chromic catgut sutures through its surrounding ligaments. The skin is closed, and the arm is bandaged to the side.

The patient may get up on the fourth day. Movements of the shoulder are not allowed for six weeks.

CASE-RECORDS

CASE 1.—An African lance-corporal, aged 24, was admitted to a military hospital on Feb. 12, 1945, with a dislocated right shoulder. This was reduced without an anæsthetic.

He gave a history of an original injury while playing rugby football in September, 1943, when he fell on the back of his right shoulder and dislocated it. Since then the shoulder had dislocated many times and had been reduced sometimes with an anæsthetic, sometimes without.

On examination on the 15th he was a small well-developed young man. His right shoulder had full range, active and passive, and power was good. Radiograms of the shoulder were normal.

On the 28th an operation as described above was performed. The glenoid fibrocartilage was found torn from the anterior glenoid rim, which was smooth and bare.

His arm was bandaged to his chest wall for six weeks, and then active movements were begun. Four weeks later he had full range of movement of his shoulder. He returned to South Africa six months later, during which time there had been no recurrence.

CASE 2.—An Indian soldier, aged 26, was admitted to an Indian military hospital in February, 1945, with a history of recurrent dislocation of right shoulder. Examination showed full range and power in his shoulder, and a radiogram was normal. He dislocated his shoulder in the ward a few days later while putting on his coat.

Operation on March 12 showed that the glenoid fibrocartilage had been separated from the anterior glenoid rim and had not reattached itself. An iliac bone graft was inserted. The shoulder was immobilised for six weeks, and then active use was begun. He was slow in regaining full range, and three months later had 20° of limitation of full elevation. There was no recurrence within the first six months, and he then returned to India.

CASE 3.—An Italian cobelligerent, aged 22, was admitted to a British military hospital on Sept. 28, 1945, with a dislocation of left shoulder following an injury in a fight the previous night.

Radiography confirmed a subcoracoid dislocation, which was easily reduced without anæsthesia. He gave a history of an original dislocation following a parachute jump in 1942, when he landed on his left shoulder. Since then there had been about ten recurrences, some of which were reduced by the patient.

Radiography showed some irregularity and absorption of the anterior glenoid lip, and absorption of bone on the postero-lateral aspect of the humeral head.

On Oct. 5 the left shoulder-joint was exposed, a raw anterior lip of the glenoid fossa seen, and an iliac bone graft inserted. The graft projected $^1/_3$ in. beyond the glenoid margin.

Six weeks later active movements of the shoulder were begun. Patient's improvement was slow. Six months later he had had no recurrence of his dislocation, but there was limitation of full elevation by 20°. Both he and case 2 were poor patients and did not try hard to rehabilitate themselves.

COMMENTS

Though those surgeons who follow Bankart's technique may not wish to change, it is suggested that they would find the iliac graft method useful when the capsule is *thin, short, or friable* ; when the bore holes cut through the bone ; or when there is old damage to the anterior glenoid rim, with displacement and consequent difficulty in drilling.

The three cases described here have not been followed sufficiently long for the final result to be assessed, and, owing to the war, it will be impossible to review them later (case 1 being an African, case 2 an Indian, and case 3 an Italian). However, the operation has been performed many times on the Continent, and Thomasen (1944), in a review of the literature, states that after 169 recorded bone-graft operations (Eden-Hybbinette) only one recurrence was recorded.

SUMMARY

The operative procedure for the treatment of recurrent dislocation of the shoulder by an anterior iliac bone graft is described.

Three cases are reported.

This operation is especially indicated where the capsule is thin and friable, and when there is difficulty in Bankart's operation in drilling the anterior glenoid rim.

". . . In times past, the doctor's field was shared, and productively tilled, by saint, monarch, *mountebank*, cleric, apothecary, and astrologer. Surgery waited upon stellar manifestation of divine approval, and epidemic disease was a visitation. Witches poisoned the patient during the doctor's absence, and demons strangled the sick. Anyone could concoct the simple drugs, conveniently drawing upon the materials of hennery, orchard, weed-patch, stable, and meat-stall. The physician's concept of human function was based upon a system inherited from philosopher and scholastic His notion of bodily structure was tinctured with these same beliefs, and included no knowledge of cellular composition. Man didn't even stay human ; he did not remain fixed in his proper phylum; he could be amphibious, arboreal, or subterranean. It was a world whose *malleability* was disconcerting to the doctor."—BARRY J. ANSON, *Quart. Bull. Nthwest Univ.* 1947, 21, 1.

Medical Societies

MEDICAL SOCIETY OF LONDON

AT a meeting of this society on Feb. 10, with Sir PHILIP MANSON-BAHR, the president, in the chair, a discussion on the

Surgical Treatment of Pulmonary Tuberculosis

was opened by Dr. GEOFFREY MARSHALL. Forty years ago, he said, there was an iron curtain between the physicians, who treated intrathoracic tuberculosis, and the surgeons, who treated tuberculosis elsewhere in the body. The physicians used only constitutional treatment and the surgeons only surgical treatment; and both got bad results.

About 1912 Rollier showed the amazing results obtainable with constitutional treatment in surgical tuberculosis. The next big advance was the introduction of the artificial pneumothorax; but physicians found themselves often frustrated by pleural adhesions. The problem was referred to the surgeons, who responded magnificently, changing the whole outlook in the chronic destructive type of disease.

In the treatment of cavitation, collapse therapy is essential; and only a minority get a lasting result from artificial pneumothorax without further intervention, usually consisting in the division of adhesions. Surgeons are sometimes reluctant to intervene when tubercles are seen on the pleura and adhesions, but even when these are present results are quite good. Often an artificial pneumothorax is not obtainable at all owing to dense adhesions, but it is essential to collapse the lung: "My experience is that if you do not close the cavity the patient will not recover." Of patients with uncollapsed cavities, 85% die within five years, while the remaining 15% survive to spread infection. It is true that the cavity disappears with two or three years' bed-rest; but it reappears when the patient gets up.

It used to be said that before thoracoplasty the patient should first be stabilised, in accordance with the principle that there was never any vital cause to hurry the operation. But the modern thoracoplasty, conducted in many stages by a team, is less dangerous and less of an ordeal, though it remains a trying and disfiguring operation.

Apicolysis has no place in present-day treatment. The operation for extrapleural pneumothorax is dangerous, patients often having a stormy passage in the first few weeks; but in those who survive it the results are almost ideal if the cavity is in the upper lobe. Better criteria for the selection of cases are needed.

Interruption of the phrenic nerve by crushing, the effect of which lasts 3 to 18 months, is ineffective with large cavities. It is, however, a safe and useful operation in the hands of the chest surgeon, and is particularly applicable to the symptomless cases now being picked up by mass radiography. When these young people are treated with simple bed-rest the lesions sometimes enlarge, perhaps proceeding to actual cavitation. An artificial pneumothorax can be done, but this is a two-edged weapon whose use is contrary to the dictum that the treatment should not be more dangerous than the disease. If there is some improvement with initial bed-rest phrenic interruption should be tried before pneumothorax.

PATHOLOGY OF CAVITATION

Mr. C. PRICE THOMAS said that the whole problem facing the surgeon in pulmonary tuberculosis is the problem of cavitation. The tuberculous cavity is from the first a tension cavity; the capillaries in its walls are also under tension, so that blood, instead of going to the cavity wall, goes to the nearby capillary bed. The cavity does not persist because of tuberculosis, but tuberculosis persists because of the cavity. "It is absolutely necessary to close tuberculous cavities."

Healing may be either "closed" or "open." Some small cavities may close by drainage through the bronchus. Usually, however, they close by closure of the bronchus; this is followed by absorption of air from the cavity, reduction of the tension, improved blood-supply, and healing. All cavities heal by the same principle. Where the patient is treated only with rest it is conceivable that the partial stenosis of the bronchus may become, with quiet inspiration, an absolute functional stenosis; otherwise the cavity will persist. All other methods depend on active relaxation. The best method is a complete artificial pneumothorax, with which 95% of cavities close. It should be remembered that with lateral thoracoplasty there is only lateral relaxation, and the vertical stress persists; the result therefore depends on the position of the bronchus or bronchi ending in the cavity.

Only two methods approximate to the perfect pneumothorax—thoracoplasty with extrafascial apicolysis, and extrapleural pneumothorax. Phrenic crush is effective against recent cavities under one inch in diameter. It has been observed with artificial pneumothorax that the diseased areas relax most—which makes the long-range effect of phrenic crush more understandable. Patients must be carefully selected for this operation, since once it has been done the risk of basal collapse following further intervention is greatly increased.

The extrapleural pneumothorax is effective, again given proper selection; but the idea of it as a substitute for thoracoplasty is to be deprecated. The morbidity and mortality tend to be under-rated; in 58 cases the mortality in the early phases was 15%; and 7 of the patients got tuberculous empyemas, 4 of which persisted. Pleural adhesions represent an attempt to get an extra blood-supply from the periphery; and it is important to select patients with early lesions (when the central blood-supply is not impaired). The operation should not be undertaken when it is likely to be difficult. When successful it is very satisfactory, providing a perfect pneumothorax without the changes in volume associated with the usual artificial pneumothorax. Experience shows that toxæmia is controlled more quickly and that cavities close more rapidly. However good the result from the extrapleural pneumothorax, it is a mistake to abandon it deliberately.

Thoracoplasty is a more definitive operation; but if it is done well and the disease is controlled no further treatment is needed—which is more than can be said of any other treatment. The depressing effect of the deformity can be minimised by gaining the patient's confidence before the operation. Cavity-closure ensues in 85–90%. The early mortality in Mr. Price Thomas's experience is 11·6%, and the late mortality 21·6%; mortality among the "stable chronics" is 8%, among the "relapsing chronics" 15·8%, and among the "slipping chronics" 55%. When the operation is undertaken during the first two years of the disease the early mortality is 1·9% and the late mortality 4%. The surgeon should be called early; and the guiding principle should be, "once you've put your hand to the plough don't turn back. Never take risks at the patient's expense; difficulties are for surgeons—not for patients."

DISCUSSION

Dr. A. HOPE GOSSE said that the operation of phrenic crush needs considerable experience and skill. Of a series of young people with early lesions treated in this way all except one now have sputa free of the tubercle bacillus; and, with this one exception, the cavities have closed. For this treatment the lesion must be early and unilateral, and the cavity narrow-walled and with a diameter not much larger than a florin. Any patient suitable for an artificial pneumothorax should first have a phrenic crush; the need for an artificial pneumothorax should be assessed after one month's interval. In this way some patients are saved the tedium and the risks of a pneumothorax.

Dr. R. R. TRAIL thought it apposite that the discussion should take place at a time when "a rather foolish correspondence" was going on in THE LANCET. He had never given up his faith in the surgical treatment of pulmonary tuberculosis.

Dr. JOSEPH SMART said that without a free pneumothorax it was not possible to get the concentric relaxation which was so important. He had often divided adhesions when tubercles were present on the pleura; and usually the reaction was no more severe. In any case the patient was better off with a free pneumothorax. As for the dangers of extrapleural pneumothorax, he thought the crux of the matter was the selection of cases. Given proper selection the results were quite dramatic.

Mr. R. C. BROCK could not think it safe to divide adhesions in the presence of tubercles; it was hard to assess the age of adhesions. A French surgeon had told him recently that he was doing one hundred cases of extrapleural pneumothorax a week; but perhaps the cases at the Brompton were not as favourable for this operation as those in sanatoria on the Continent. It was a dangerous operation, and he was not sure that the results on the Continent were better than in Britain. The disadvantage of replacing thoracoplasty by extrapleural pneumothorax was that a thoracoplasty had often to be done afterwards. If the patients were carefully looked after the deformity from thoracoplasty was usually negligible; in any case it was better to be deformed than dead. The dictum that delay in thoracoplasty is always desirable was "horrifying." In his view the critical phase in the life of the patient with chronic pulmonary tuberculosis was when he left the sanatorium for the first time: unless his disease was completely controlled by a perfect pneumothorax he was unsafe; and if surgeons would only step in with thoracoplasty much better results would be obtained. As for pneumonectomy, he was feeling his way gingerly, and the few cases he had done had been very carefully selected.

In reply, Dr. MARSHALL said that in the treatment of bilateral cavitation thoracoplasty was a dangerous remedy; but this was a dangerous disease. A thoracoplasty on one side and an artificial pneumothorax on the other was much less dangerous and was often highly successful. Mr. PRICE THOMAS said that about half the patients he operated on had bilateral disease. On the subject of pneumonectomy he was as cautious as Mr. Brock.

Reviews of Books

An Approach to Social Medicine

JOHN D. KERSHAW, M.D. Lond., D.P.H., medical officer of health, Accrington. London: Baillière. Pp. 329. 15s.

THIS book seeks "not to teach the reader social medicine but to show him where it lies and how it may be sought." The first half could well stand by itself as a description of the origin and purposes of our social fabric; in the second half Dr. Kershaw indicates the place he would give to medicine in this larger framework. Since medicine entered late into the scientific field, doctors followed the lead of their colleagues in the physical sciences, and adopted a mechanistic outlook—to the neglect, he suggests, of philosophy. Yet we must not forget that it was the sharp reaction from earlier unfounded theorising which gave us the hard facts on which we build today. This thoughtful book gives the casual reader a good idea of medicine's widening functions in a changing world; for those who wish to make a serious study of social medicine there could be no more encouraging introduction.

The Psycho-analytic Theory of the Neuroses

OTTO FENICHEL, M.D. London: Kegan Paul. Pp. 703. 35s.

THE author of *Outlines of Clinical Psycho-analysis*, published in 1934, rather than produce a second edition, has completely altered his previous book, and added a general introduction, a bibliography of over 1600 references, and an index of 40 pages. His facility in writing, which survived translation in the former book, is preserved now in his own English. His useful book not only covers many points of Freudian theory but illustrates the divergences of the psycho-analytic discipline from formal psychiatry. Thus "traumata" are never "physical," they are associated with castration and implied insecurity, and the intellectual and physical factors which form so important a part of Meyer's "psychobiology" are hardly mentioned. The index has only three references to the climacteric, three to "physical" matters, seventeen to the "body," and twenty to "organic" conditions; "neurology" is not indexed at all, and the thalamic centres and the sympathetic nervous system not even mentioned. The title of the book may justify this dichotomy, but the rift between neurology and psycho-analysis has not been bridged by Dr. Fenichel, able writer though he is; and we could wish he had written the book of a dweller in both worlds, like Stanley Cobb's *Foundations of Neuropsychiatry*.

He is notably frank in discussing contra-indications to treatment and trial analyses, but offers no suggestions for shortening psycho-analytic treatment. He emphasises the emotional character of "shock," but later admits that insulin and leptazol act best on different disorders, thus implying that the word "shock" itself may have other connotations. Similar and more serious difficulties may be found in formulations about the origin of the ego; but, open to dispute as these may be, his clarity in general and his careful documentation make the volume essential for the psycho-analyst, and to others a valuable book of reference.

Gray's Anatomy

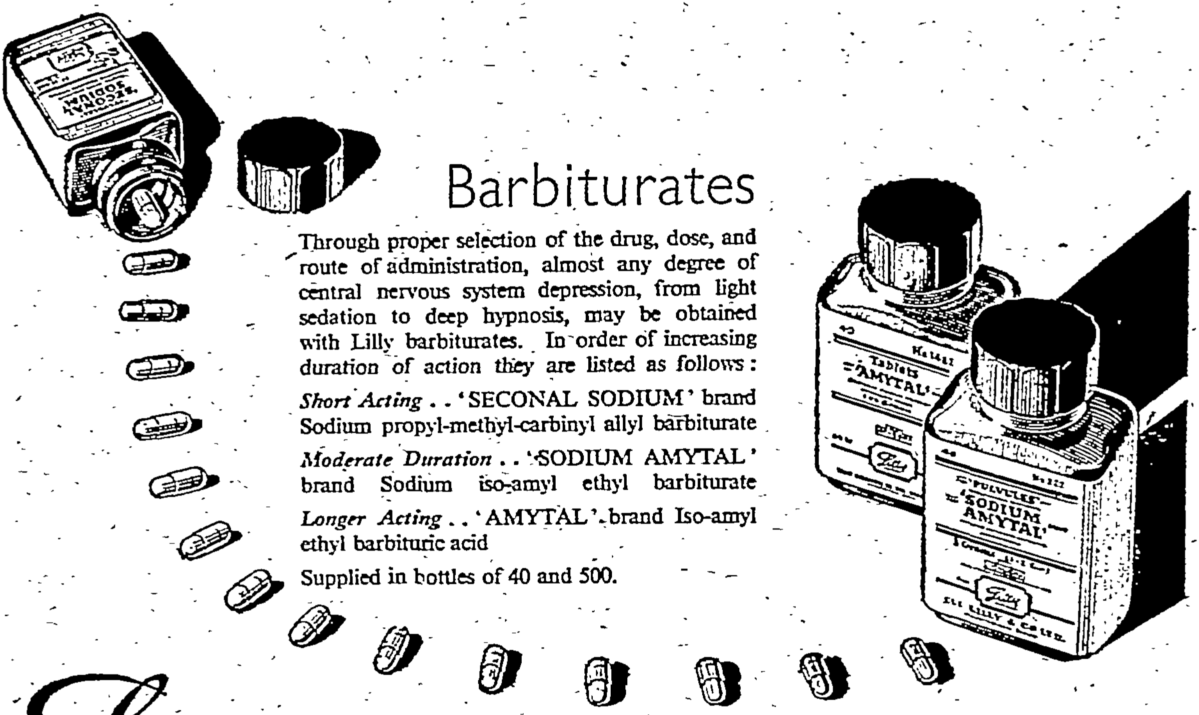
Descriptive and Applied. (29th ed.) Editors: T. B. JOHNSTON, O.B.E., M.D.; J. WHILLIS, M.D., M.S. London: Longmans, Green. Pp. 1597. 70s.

THE basic facts of topographical anatomy have not altered since Gray wrote his first edition in 1858, yet his book has now reached its 29th edition—roughly a new edition every three years. "Gray," containing as it does sections on histology, embryology, and neurology, all subjects which are rapidly progressing, is more than a reference book of topographical anatomy; and it is largely because these sections must be kept up to date that new editions are needed frequently. Though there are advantages in having all branches of anatomy collected together in one reference work, few medical students rely on "Gray" for their histology, embryology, and neurology; but if these sections are to be included it is important that they should be factual and accurate, without too much discussion of controversial subjects or unlikely theories. In this edition, for example, perhaps too much space is devoted to Carey's theory of muscle structure, which is far from being generally accepted; but Sharpey-Schafer's classical diagram of the sarcomere has at last been omitted. The picture of a spermatozoon is drawn at a magnification well beyond the resolution of any ordinary microscope and is therefore misleading. In future editions electron microscope pictures should replace such diagrams. It is impossible for the authors to please everyone, but a discussion of blood-groups, and especially of the Rh factor, seems out of place in an anatomy book. Much new matter has been added, including sections on the work of Holmes and Young on nerve regeneration, of Weddell and Woollard on cutaneous innervation, and of Brock on the bronchial tree. Apart from drawbacks due to poor paper, most of the illustrations are first-class, and many new ones have been added. The X-ray plates too are good, and we could do with many more.

Entstehung und Früherfassung des Portiokarzinoms

Dr. med. HANSJAKOB WESPI, Chefarzt der geburtshilflich-gynäkologischen Abteilung am Krankenhaus Frauenfeld. Basle: Benno Schwabe. Pp. 91. Sw. fr. 11.

THIS book is concerned with the early diagnosis of cancer of the uterine cervix by means of the Hinselmann colposcope. The author, who has charge of the gynæcological clinic of the University of Zurich, has for seven years been using this method, together with the Schiller iodine test, to establish the diagnosis in early and difficult cases. The colposcopic picture and the histology of the normal and pathological cervix are carefully described, and the various types of white leucoplakia, red erosion, and irregular surfaces which may be seen are usefully discussed. Case-records show the care which is taken in the examination of every patient whose condition gives rise to suspicion of early neoplasia, and illustrate the possibility of distinguishing between certain early cancers and simple inflammatory conditions. The numbers of patients with cancer of the uterine cervix who can be treated early and with success are increased when routine colposcopic examinations are made. Such close observation is only possible, however, where facilities such as those offered by his clinic are available; and gynæcologists in Switzerland seem to be fortunate in seeing many of their cases at a stage when the diagnosis is still in doubt.



Barbiturates

Through proper selection of the drug, dose, and route of administration, almost any degree of central nervous system depression, from light sedation to deep hypnosis, may be obtained with Lilly barbiturates. In order of increasing duration of action they are listed as follows:

Short Acting . . 'SECONAL SODIUM' brand Sodium propyl-methyl-carbinyl allyl barbiturate

Moderate Duration . . 'SODIUM AMYTAL' brand Sodium iso-amyl ethyl barbiturate

Longer Acting . . 'AMYTAL' brand Iso-amyl ethyl barbituric acid

Supplied in bottles of 40 and 500.

Lilly
TRADE MARK

ELI LILLY & COMPANY LIMITED, BASINGSTOKE & LONDON

When Convalescence
begins . . .

the problem of finding a stimulant that is both effective *and* palatable is solved by Burgoyne's Tintara. It is a pure wine, acceptable to the most delicate and made from grapes grown on ferruginous Australian soil.

Supplies are unfortunately limited for the present, but every effort will be made to meet urgent cases.

Burgoyne's
TINTARA BURGUNDY

A naturally pure wine—no added alcohol or sugar

ANTUITRIN 'S'

(ANTROIDIN)

A standardized solution of chorionic gonadotrophin obtained from human pregnancy urine

IN the female the effect of Antuitrin 'S' is mainly luteinizing, and it is indicated in functional uterine bleeding, dysmenorrhœa, amenorrhœa, oligomenorrhœa, and habitual and threatened abortion.

In the male Antuitrin 'S' acts on the interstitial cells of the testes, increasing secretion of the male hormone, and is used in the treatment of cryptorchidism, impotence, and aspermia.

In both sexes it has been shown to be valuable in delayed puberty, genital infantilism, acne vulgaris, adipose-genital dystrophy (Fröhlich's syndrome), and in some cases of sterility.

Packages

Antuitrin 'S' is supplied in rubber-capped vials of 10 c.c. (100 International units per c.c.) and 5 c.c., Concentrated Solution (500 International units per c.c.)

LONDON: SATURDAY, MARCH 22, 1947

Service Medicine

It is generally agreed that during the late war the medical services of the Armed Forces did their job remarkably well; but it is also generally agreed that their organisation left much to be desired. Many obstructions were broken down by forceful individuals of strong character, accustomed to insist that what was necessary must be done. But many tiresome arguments arose because the prevailing atmosphere in the regular Services—hard to define, perhaps, but impossible to ignore—does not at present encourage professional zeal and initiative. Further, the regular medical officer—with all respect to many admirable doctors—seldom enjoys such professional standing that he can confidently challenge even unenlightened orders or regulations.

This brings us to consider the nature of the authority which directs the medical services of the Armed Forces. The first astonishing discovery in this connexion is the absence of any single authority. The sailor, soldier, and airman, it seems, are such different persons that separate organisations are required to keep them in health and attend to their sicknesses. Yet the Navy, Army, and Air Force comprise a limited age-group, they share alike the stresses of tropical service, and their principal medical objective is the maintenance of health.

The consequence of having three small separate medical services, rather than one large organisation for the three branches, is best studied in the Army—the largest consumer of medical man-power. One bad result is that the Director-General of Army Medical Services is not a member of the Army Council. He makes his views known to the Army Council only through the Adjutant-General, who, however well informed he may be, is a soldier and a layman and therefore not the proper person to present a medical argument. Clearly, the spokesman of medicine ought to be a professional man constantly in touch with the highest administrative and political levels. It should be his duty and within his power to see that health considerations and medical problems are kept well to the front in any discussion of policy or in planning a campaign, instead of being fitted in after the main lines have been settled. The lack of status now accorded to Service medicine is further emphasised by the fact that the Director-General of Army Medical Services receives the rank of lieutenant-general. He is thus a person of less authority than the commander of a force of any size—of less authority, for example, than the chief of anti-aircraft command—and he does not, therefore, talk to important field commanders on equal terms. It is accordingly difficult for him to exercise what should often be a decisive influence, and many necessary enterprises—such as the field trial of penicillin in war wounds—have to be tactfully engineered on an "old boy" basis, often with resulting delay and frustration, instead of being organised with authority from the War Office. Devolution of authority to the man on the spot is an excellent principle, but one that can be carried too far. In a campaign the final medical authority is vested in the commander-in-chief, who acts (or does not act) on the advice of his own director of medical services—an officer junior to the Director-General of Medical Services at the War Office, yet not under his control. In short, London may offer advice and arrange for the supply of men and equipment, but it lacks medical authority.

Manifestly this is absurd. Medicine must speak as an equal in the highest counsels of the Armed Forces, and the health needs of sailors, soldiers, and airmen must be rated much higher than hitherto. It is as important, and as difficult, to plan strategically against malaria, dysentery, and anxiety state as to plan against attack by enemy aircraft.

Our plea, repeated yet again,[1] is for unification of the medical services of the Navy, Army, and Air Force under a single head, with rank corresponding to that of a full general. All who know Service medicine are conscious of the need for a great raising of professional standards such as can come only from combined planning for the complete medical needs of all three Services—real planning at the highest instead of the second-highest level. We need a training school for Service medical officers which will bear comparison with that of the Americans; we must avoid wasteful competition among the three Services for our too few doctors [2]; and we must have every activity of the Service chiefs and the Treasury subjected to authoritative medical comment offered directly—by doctors on equal terms. If the Navy, Army, and Air Force medical services do not themselves move towards such fusion as would be natural under the new Ministry of Defence,[3] it seems to us that pressure ought to be applied when the National Service Bill comes before the House of Commons.[4] The medical group in the House and perhaps also the presidents of the Royal Colleges, who will have access to full information about the state of British military medicine from their members who served the Forces as consultants, might reasonably ask the Minister of Health to consider whether, after all, he was wise to leave the Armed Forces out of consideration in making his plans for a comprehensive health service for the nation.

Postoperative Pulmonary Embolism

DESPITE almost exactly a century of study—for VIRCHOW established the nature of pulmonary embolism in 1846—there is much concerning this disastrous condition which remains mysterious. Fatal embolism is fortunately uncommon: though the majority of cases come to necropsy, the average incidence in post-mortems at general hospitals is less than 2%. It is moreover an affliction of mature years, almost unknown in childhood and adolescence, and rare in the twenties and thirties; nearly all the victims have been ill in bed for a long time, and more than two-thirds of them have had a serious operation within a fortnight; and often the embolism is merely the immediate cause of a death in any case soon inevitable. Nevertheless about a quarter of all the deaths are in patients who have had no operation at

all, but suffer from such conditions as varicose veins and valvular disease of the heart.

It is the surgical cases that present the most dramatic picture. The patient perhaps was a man of 60, who had lain abed for months and had then had a gastrectomy. Convalescence was unsatisfactory; there was a low fever; he appeared anxious, and was a difficult man to nurse. Twelve days after operation, when he was becoming more active, he called for a bedpan, was found to be severely shocked, and died within a few minutes or hours At necropsy the cardiac blood was fluid; but a massive clot filled both pulmonary arteries, and small thrombi could be expelled by pressure from the smallest vessels. We ask ourselves where and when did the clot form. Why did it form? Why did it move from its original site? Most urgently, what can be done to prevent the accident?

The pendulum has swung many times since VIRCHOW first suggested the pelvic veins as a site of the thrombosis, and since WELCH,[1] who began twenty years of study in 1887, demonstrated that the deep veins of the leg were often involved An important further step has been the distinction between thrombosis in phlebitis, where the clots are firmly attached and seldom move, and thrombosis in undamaged veins, which does not cause œdema but carries a far greater risk of embolism Some have supposed that this latter type of thrombosis in calf-muscle veins results from retrograde spread; others that the small veins in the soleus muscle, which itself is said to show degenerative changes, are the primary site. Latterly the work of HUNTER and other American investigators[2] has forcibly directed attention to this muscle; and all who have looked agree that a remarkably high proportion of bedridden patients—more than half in some hospital records—have these clots, though in one series, where over 50% showed them, only 3% died of embolism. BAUER[3] in Sweden, by phlebography, satisfied himself that the clots form in the deep veins of the leg, and sections at various levels suggest that the oldest clots are in these deep peripheral veins. But if this is accepted, we still have to ask why they form there. Mere immobilisation is not enough: though supports behind the knees, or abnormal postures during operation, may aggravate the condition, plaster casts do not cause thrombosis or embolism And if the majority of elderly patients kept abed with chronic illnesses develop these clots, we cannot very well hold surgery responsible for their formation, but only for their movement, and perhaps their enlargement Here the work of MACFARLANE, begun in 1937 and now continuing,[4] may prove of critical value He has shown that a fibrinolysin can be identified in the plasma of patients after operation; that is to say, the fibrinolysin always present is activated in such patients; and he has made the fascinating observation that fibrinolysin activation depends less on trauma than on a state of anxiety—which might explain the higher incidence of pulmonary embolism during air-raids. Equanimity has more than a moral value, and the bedside manner may extend its balm even to the veins of the soleus muscle.

How can pulmonary embolism be prevented? In the first place, every surgical patient of mature years must be considered a possible candidate Massage of calf muscles and active movements of the leg are advisable both before and after operation, and prolonged preoperative decubitus should be avoided. Dilatory operative technique and dilatory operation are dangerous: peace of mind, confidence, and a calm environment are to be promoted. Pain on palpation of calf muscles and hyperextension of the foot will suggest that thrombosis is already present, and in such circumstances American practice favours ligation of the vein and extrusion of thrombi, though it is hard to know whether this is effective Anticoagulants are in a different class; and in spite of its expense many believe that heparin should be given prophylactically to a large proportion of patients after operation. Presumably its action would be to prevent proximal spread of deep thrombi, for if the large veins are already involved its use might be risky.

We have travelled a long way, then, since VIRCHOW'S observations a century ago. When we know the cause of fibrinolysis we may perhaps control the dislodgment of clots.

Atypical Smallpox

SMALLPOX is an import we could very well do without. Between January and June last year 55 cases of variola major were recognised in England,[1] and 15 of these were infected in or en route from India The remaining 40 cases were certainly infected in England, and though a direct connexion with a known imported case could be established in only 7 of these, the other 33 were grouped into ten separate outbreaks all of which occurred in districts and at times which suggested indirect association with cases known to have been ship-borne During the second half of 1946 the importation of fresh infection apparently ceased and there were no further indigenous cases, but it looks as if the events of last spring are now being repeated The first 2 cases recognised in the present outbreak at Grimsby, where there have so far been 15 cases with 6 deaths, were permanent residents of a common lodging-house frequented by sailors. These 2 men were taken ill on Feb. 13, and the source of infection was probably one of a number of seamen who stayed at the lodging-house for a night or so early in February. On March 3 a member of the staff of a large seamen's hostel in Stepney developed what was later recognised as smallpox modified by vaccination Here again the undetected source of infection was probably a seaman.* No link has been discovered between the two outbreaks, but both seem likely to have originated in modified or atypical cases connected with ships from abroad.

Atypical smallpox, sometimes with an almost negligible focal eruption, is not uncommon in vaccinated people whose immunity has waned or in whom revaccination has for one reason or another been ineffective. As **Stallybrass**[2] has remarked, immunity to smallpox, whether produced by artificial or natural means, is not a mathematically precise process, and there are considerable individual variations in the solidity and permanence of the resultant increase in resistance. Moreover, immunity to smallpox cannot yet be measured or even roughly assessed by skin or serological tests as can that to diphtheria. In discussing difficulties in the diagnosis of atypical cases **Conybeare**[3] has drawn attention to the help now obtainable from the laboratory tests recently described in detail by **Downie**.[4] It is not surprising that some atypical cases with a minimal focal eruption go completely undetected, since these people may never be sufficiently ill to call a doctor. After two or three days of malaise with headache and fever, at this time of year easily regarded as influenza, they suddenly feel better and may not pay any attention to the few spots—often not more than a dozen—which have appeared usually on the forehead and about the wrists or backs of the hands. In this infectious stage they go unhindered about their work and social occupations. So unless and until a more florid form of the disease appears in some person with a weaker immunity the presence of smallpox in a fairly well vaccinated community may remain unsuspected and all chance of tracing its origin may be lost. Even when smallpox is already in mind the clinical diagnosis of cases with a minimal focal eruption may be extremely difficult. Significant points are the prostration associated with the pre-eruptive illness, even when the rash itself is almost negligible, and the sudden cessation of the constitutional disturbance when the eruption appears. The centrifugal distribution of the eruption remains the sheet anchor of smallpox diagnosis; but the fewer the lesions the less evident is this characteristic pattern. The lesions of a minimal eruption lack the uniform shape and orderly development which are useful guides in a more pronounced rash; they also tend to be relatively superficial in the skin and to mature rapidly or sometimes to abort without pustule formation. Atypical smallpox should be seriously considered when papular lesions, however few, some of which have rapidly acquired vesicular or pustular heads, suddenly appear about the face, wrists, hands, or feet of any vaccinated person who has just recovered from so-called influenza In most cases of this sort the clinical diagnosis, even when made by an expert, should be checked by laboratory tests.

---

[1] Maddock, E. C. G., Conybeare, E. T. *Mon. Bull. Min. Hlth & E.P.H.L.S.* 1946, 5, 224.

* Rather than a woman, as was mistakenly suggested in an annotation last week (p 339).

The focal eruption of smallpox may be more or less profuse and yet remain in some respects atypical. Such cases nearly always come under medical observation and are not often completely overlooked though they may be misdiagnosed, usually as chickenpox. In these, careful attention to the distribution pattern of the mature rash and to the nature and development of the lesions, plus the history of the pre-eruptive illness, will usually be sufficient for a confident clinical diagnosis; but here again the help of the laboratory is not to be despised. It is worth noting that in some of the Grimsby cases the distribution pattern of the mature eruption has been typical but the order of the outcrop has been unusual in that the initial lesions were on the body.

Another form of smallpox which may not be promptly recognised is the severe toxic hæmorrhagic type which is sometimes fatal before the delayed focal eruption appears. Such patients are critically ill with extreme prostration. They usually have a diffuse erythema, sometimes with petechiæ or purpuric spots over the bathing-drawers area, and conjunctival hæmorrhage is common These cases may be admitted to hospital as scarlet fever, measles, or septicæmia. Although usually unvaccinated, the patients sometimes give a history of a successful vaccination in childhood without revaccination; for infant vaccination does not necessarily provide lifelong protection against this severe and almost invariably fatal form of smallpox. At times like the present, when smallpox is prevalent, the medical staffs of hospitals should be specially on their guard against the inadvertent admission of such cases to open wards.

Annotations

BEFORE OR AFTER?

The essence of the National Service Bill now before Parliament is that all men between 18 and 26 years of age shall be liable to 18 months' full-time military service, to be followed by 5½ years' part-time service during which they may have to undergo a total of 60 days' further training. Postponement of service is mentioned, though the grounds for postponement are not defined; and for doctors and dentists who are working for additional qualifications the age-limit for call-up is extended to 30. The 8-year span of liability may perhaps be necessary to include any who through illness or for some other reason cannot be recruited in their teens: but it leaves the young man uncertain as to when he will have to serve, and all would welcome a specific assurance that this latitude will not be used to gratify the administrative whims of Service departments. The wide sweep of the age clause enables the Minister of Labour, if he wishes, to defer the call-up of medical students until they are qualified; but we are not told whether this will in fact be done: and he might hold that by keeping such students in line with others he would avoid the perils of establishing a privileged group.

Before qualifying, the medical student has six years of arduous, expensive, and unpaid work; and, by an unhappy tradition, the young doctor often receives only an apprentice's salary for the first few years. Hence the price paid by nearly all who elect to study medicine is the deferment of marriage and a settled home; and if military service is to be interposed before medical training the possibility of marriage may be yet further postponed. Some medical educationists[1] approve of an interlude of military service, between school and medical school, because it broadens the student's outlook and improves his judgment; but it amounts to an addition of nearly two years to the curriculum, which could only be tolerable if the methods of paying young doctors were changed so that they could support a family soon after qualifying.

That is of course mainly a professional matter. But there are also strong national reasons for postponing the military service of medical students until they have qualified. Presuming that in time of war they are going to be used as doctors, can we doubt that a period of training in Service medical work, with responsibility for the care of troops, will stand them in better stead than a corresponding period of general training at 18 years of age? Is it economical to teach young men to drive tanks, or look after aircraft, or keep naval stores, when they are going to be employed as medical officers? Few will deny that the future doctor, like anyone else, will gain much by serving in the ranks; and if it were administratively possible there is something to be said for the suggestion[2] that his military service should be done in two spells—one after leaving school and the other after qualifying. But if the choice is between service entirely before medical training or entirely after it, the latter appears more advantageous to the Armed Forces themselves.

---

[1] See *Lancet*, 1946, ii, 305.

It is also less wasteful to the community as a whole. The latent shortage of doctors will become manifest when the National Health Service comes into operation, and this shortage cannot be overcome for many years because of the insufficient capacity of our medical schools. Until (if ever) there is a surplus of doctors, every man or woman who has passed successfully through a medical school must be regarded as a national asset. The effect of calling up men before military training is to subtract at least 18 months from their professional working lives, and such wastage of medical educational resources should be avoided if possible. The Services may say that in peace-time they could not find work for all the men who qualify in medicine each year; and the emphasis might have to be on training and observation of Service medical methods rather than on active employment for all. But is there any reason why a considerable proportion of these young men should not be seconded for part of their time to the Colonial Medical Service or indeed to any other national service which has need of them?

The medical schools can turn out only a limited number of doctors each year, and the greatest advantage will be gained if these qualify at the earliest age that they are competent for their work. Even with this principle conceded, they must still undertake "national service," but we hope that in course of time the present narrow connotation of that term will be extended (as it already has been with miners) and that it will come to include work in civilian hospitals abroad or even at home. If the different Government departments begin to compete for the services of young doctors, the Medical Priority Committee would be the right body to judge between them, and it will gain wide support if it tries to arrange a realistic distribution.

THE STEVENS-JOHNSON SYNDROME

THE rare syndrome of which two examples were described in these columns last week by Dr. Murray and Dr. Nellen is one of the conditions which may lead the doctor to suspect smallpox and the smallpox expert to say: "It isn't smallpox, but I don't know what it is." First noted in France in 1822 by Alibert and Bazin, it was not until a century later that Stevens and Johnson[3] in the U.S.A. drew attention to its characteristic features—swinging fever, skin rash, stomatitis, and ophthalmia—though Hebra had included it in his *Diseases of the Skin* of 1866 under the name of erythema exudativum multiforme.

It is found almost exclusively in boys or young men. The rash is usually but not always preceded by several days of gradually increasing cough, malaise, headache, and vomiting. The distribution of the rash is mainly peripheral, the dorsum of the hands and feet, the forearms and legs, and the face being the sites of election. It starts as macules or papules about 1·5 cm. across, each surrounded by a ring of erythema; later, vesicles appear, followed by crusts which leave little or no mark. As a rule the rash does not itch. For about the first week the temperature swings between 102° and 105° F, after which it falls to around 99° F. The most unpleasant and dangerous part of the illness is the swelling and infection of mucous membranes, particularly of the conjunctiva, mouth, and urethra. The tongue and lips may swell to twice their normal size, and the eyes may be up with pus; the Rosenbergs draw attention to the air of dejection which these swellings give to the patient. Partial or complete blindness is a common sequel, resulting from corneal ulceration and scarring, bilateral suppurative keratitis, and other causes.

So far, attempts at incriminating an organism have failed—Vincent's organisms have not been found regularly in the mouth, fluid taken from a vesicle of one of Dr. Murray's cases proved negative when examined for variola-vaccinia antigen, and no predominant organism was grown from a purulent urethral discharge. The ætiology must be regarded as unknown, though allergic sensitisation seems to be a factor. As regards treatment, there is not much evidence that the sulphonamides have any specific effect; whether the fall in temperature had any association with the penicillin given in Dr. Murray's case is uncertain. The most urgent measure seems to be protection of the eyes.

THYROIDECTOMY OR THIOURACIL?

DISCUSSION of toxic goitre nowadays centres round the place of thiouracil in treatment. At the Medical Society of London meeting on March 10 the balance of opinion was against thiouracil; its drawbacks, said Dr. Horace Evans, are the risk of idiosyncrasy, the persistence of the tumour, and the need for protracted treatment. There is, he suggested, little to choose between the results with thiouracil and those after subtotal thyroidectomy by an expert surgeon; surely the short treatment by surgery is preferable. In his view thiouracil has its value in the preoperative preparation of iodine-sensitive patients, and in the treatment of those who refuse operation or are poor operative risks; it is a substitute for operation where expert surgery is unobtainable.

Mr. Geoffrey Keynes also preferred surgical treatment He argued that the sustained use of thiouracil, which is a dangerous drug, must mean psychic trauma to both patient and doctor. Means, of Boston, found that the condition after withdrawal of the drug was satisfactory in only 10% of over 1000 cases; and when the drug was resumed toxic reactions became more frequent Mr. Keynes mentioned cases in which thiouracil has proved ineffective or actually dangerous. Some patients with toxic goitre—particularly the nodular variety—get worse despite this treatment; some are intolerant of thiouracil; a pregnant woman treated with it may give birth to a baby with a large thyroid; and there is a possible, though unproved, risk of carcinomatous change. He preferred a carefully planned operation; in over 2000 cases operated on at St. Bartholomew's Hospital, London, the death-rate was under 1%. The trouble with thiouracil is that it does not act on the gland; by depriving the gland of iodine it stimulates it to further activity. Preoperative treatment with thiouracil may prejudice surgical chances, for after this treatment there is often torrential hæmorrhage at operation. Thiouracil may be of value in the preoperative treatment of patients whose condition is really acute, otherwise its use means loss of time and effort, since before operation its effect has to be damped down again with iodine. To the question "Have we gained from thiouracil?" Mr. Keynes's answer was: "While the drug is being given with enthusiasm we have lost heavily. So far, on balance, there is a heavy loss."

This view was largely supported by the meeting; for the young woman with thyrotoxicosis, it was suggested, "there is much to be said for leaving the invisible scar rather than the larger goitre." Dr. Evan Bedford's faith in surgery was unimpaired: "I cannot conceive of the heart patient," he said, "who cannot be prepared for surgery with iodine; I go on with it, if necessary, for a month." The aim, when there are cardiac complications, is not only to end the thyrotoxicosis but to produce myxœdema; with primary goitres there may be a case for thiouracil, and operation, if undertaken, must be radical. As a therapeutic test, Dr. Evans held that thiouracil is useless; others thought it might have some value.

---

[3] Stevens, A. M., Johnson, F. C. *Amer. J. Dis Child.* 1922, **24**, 526.

The case for thiouracil was put by Dr. W. R. Trotter. The criterion in choice of treatment should, he maintained, be the case-mortality. The operative mortality of subtotal thyroidectomy in Mr. Keynes's series is under 1%; but the overall rate for the country is at least 5%, and there is little hope of the general run of surgeons ever gaining the proficiency of the expert. The claim for thiouracil is that if it generally superseded surgery fewer people would die. In Dr. Trotter's opinion the danger of thyroid enlargement with thiouracil has been exaggerated. If there is any swelling this simply calls for reduced dosage; but usually the gland remains the same size or actually shrinks—probably because of a natural remission. Thiouracil, he agreed, is not a radical cure; so it is probably owing to spontaneous remissions that the drug can sometimes be discontinued without symptoms recurring. He agreed, too, that thiouracil is unsuitable for nodular goitres, since most of these are already causing, or are likely to cause, mechanical obstruction.

THE FILMSTRIP IN MEDICAL TEACHING

A FILMSTRIP resembles a box of lantern slides in being a collection of pictures or texts for projection on to a screen, but here they are assembled on a continuous strip of 35 mm. ciné-film. Its uses in the training of medical students were discussed at a joint meeting of the Royal Society of Medicine and the medical committee of the Scientific Film Association on Feb. 12. As Dr. Peter Hansell pointed out, filmstrip is much lighter to carry about but more easily scratched than slides, and it is tedious to change the order of the pictures. However, a teacher can have his various illustrations, tables, texts, and charts copied on a filmstrip, slip it into his waistcoat pocket, and go off to his lecture secure in the knowledge that his projectionist cannot screen his pictures in the wrong order. If he wishes radically to alter the presentation of his lecture he must make up a fresh strip, but they are cheap enough for this not to be a serious deterrent. A special projector is necessary, and Dr. Brian Stanford emphasised that there is room for improvement in the design of those now on sale.

A more advanced concept of the filmstrip is a prepared sequence of pictures, each showing, for example, some change from the last, so enabling the stages of a process to be followed step by step. The advantage here over slides lies in the very fact that the order cannot be muddled by the projectionist, and the advantage over ciné-film is that each stage can be held on the screen for as long as the teacher desires. Indeed, he may project his pictures on the blackboard, draw in the next step with chalk, and then flick on the next picture, so building up an artist's presentation of the subject however imperfect his draughtsmanship. This technique has obvious applications in the teaching of anatomy and surgery. By extending it further, a subject, such as first-aid, may be broken down into its visual stages which are then presented at a speed convenient to the intelligence of the class. Sometimes, as Mr. J. P. Stephenson showed, no commentary is necessary, and the filmstrip will have much the effect of an animated diagram film at a fraction of the cost. Other filmstrips require verbal explanation; this may be provided extempore by the teacher or may be based on a booklet issued with the filmstrip. An example of the last class is the nutrition series issued by Common Ground Ltd., with teaching notes for school-children and fuller ones for adult audiences.

The manufacture of the more ambitious kinds of filmstrip is a growing branch of the film industry, which has specially trained artists already at its command. The making of instructional films is becoming more and more a composite function, involving the simultaneous production of strips, booklets, wall-charts, note-sheets, and even models by a team consisting of educational psychologist, practising teacher, subject expert, filmmaker, and unifying producer.

KIDNEY AND LIVER IN WEIL'S DISEASE

DIMINISHED renal function is one of the outstanding features of Weil's disease: fatal cases usually terminate with oliguria leading to anuria. This renal failure is of complex ætiology. The kidney lesion is mainly tubular and resembles the pigment kidney of incompatible blood-transfusion or crushing injuries.[1] There are at least three possible sources of the pigment. It may be bilirubin; and comparable changes occur in other forms of severe jaundice. It may be myoglobin, suggesting an analogy with the crush kidney; and severe muscle necrosis is a feature of Weil's disease.[2] It may be derived from hæmoglobin; in Weil's disease blood destruction occurring in the spleen is greatly increased.[3] In addition to the pigment effects there is also the direct action of the spirochætes on the kidney. The uræmia, however, is not only renal but also prerenal. The cardiac output is thought to be low, possibly because of the myocardial changes, and the blood-pressure falls; so there is probably a reduced renal blood-flow.

Though jaundice is the most obvious clinical finding in Weil's disease, it seems likely that hepatic failure contributes little to the fatal outcome. Hepatic lesions are, in fact, often minimal. Wylie [4] found that necrosis of the liver is an inconstant feature of experimental leptospirosis icterohæmorrhagica. Hutchinson and his colleagues [1] described five fatal cases in an outbreak in the British Army in Italy and remarked on the absence of hepatic damage. Often the liver shows only lymphocytic infiltrations around the portal tract, resembling the late stage of acute infective hepatitis. Liver-cell mitoses indicate that repair is already in progress. It may be that the maximal liver damage is early and that recovery takes place while the renal damage is still progressing. Study of hepatic histology by aspiration biopsy in the earlier stages may reveal more severe damage than in patients dying later from uræmia.

In human Weil's disease much further research is needed into the mechanism of the uræmia and the jaundice. Careful studies of the circulation and of renal and hepatic function by modern methods are still lacking: the evidence at present rests almost entirely on necropsy studies and animal experiment. Uræmia being the most usual termination, treatment should be directed to the kidney. In mild cases a minimum fluid intake of 2 litres a day with early alkalisation of the urine may be sufficient. In an anuric patient Williams [5] established a diuresis by high spinal anæsthesia, but this measure lowers the already low blood-pressure, so peritoneal lavage or use of the artificial kidney [6] may be more successful. It should, however, be remembered that Weil's disease is a severe acute toxæmia with lesions in almost every organ. Early diagnosis is essential, and, as Bulmer [7] has shown, prompt penicillin therapy may prevent the development of the serious renal complications.

OPERATION NUTS

UNLESS new action is taken, the shortage of oils and fats will continue till 1960 or even longer. Britain's deficit alone is estimated as equivalent to $1^1/_4$ million tons of ground-nuts a year. India, once the largest exporter of these, now requires for her growing population all that she produces.

The world's hunger, it has been said, is Africa's opportunity, and last summer a mission went out to examine the feasibility of East and Central Africa taking India's place as chief provider. The mission's scheme,[1] which has the Government's full support, is inspiring not only in its scope but in its implications for a hungry world and a needy quarter of the African continent. Within the next six years 3,210,000 acres of undeveloped land in Tanganyika Territory, Northern Rhodesia, and Kenya is to be cleared and planted with ground-nuts. *Arachis hypogæa,* which bears this nut (better known also as the earth-nut, pea-nut, or monkey-nut), has been chosen because, of all annuals, it gives the highest yield of oil per acre, and because its production can be almost wholly mechanised. Speed is the essence of this vast programme, and already the world is being scoured for bulldozers to clear the 150,000 acres which are scheduled for planting before the end of this year. The cost to Britain will be in the neighbourhood of £24 million, but with a probable production of over 600,000 tons from 1952 onwards we shall be saved over £10 million a year on our food bill.

As a business undertaking the plan can hardly fail: what of it as a colonial enterprise? The governments in Africa have acclaimed it, stipulating only that labour shall not be diverted from established industries, that the land shall not be exploited, and that the project shall be capable of eventual integration into the African economy. These provisos, it seems, are to be met: labour is to be drawn from areas of over-population and under-employment; the quality of the land is to be improved, and the improvement maintained by its being kept under grass for two in every four years; and control is to pass, after an agreed period, to the local governments. The report suggests—though this will be for local decision—that Africans themselves, when once trained for the task, might farm the land collectively. In direct employment the immediate benefits are not great: once development is complete the scheme will require only some 30,000 African men. Many in this and other countries, however, will judge the quality of our intentions by the conditions of life and work which these men are offered. The surveyors' recommendation, endorsed by the Government, is, so far as it goes, clear enough:

> "We consider that each of the 107 units could be so organised as to provide a centre for the introduction of improved standards of housing, health, nutrition and welfare, in short, as a model of better general standards of living for the African people. The adoption and maintenance of these standards should not present any insuperable difficulty since the project will from the outset provide housing, medical attention and welfare for these new communities and will also produce or procure for them the bulk of their staple foodstuffs."

Establishment of these new communities will be no small task. Families coming from different areas may not take kindly to mixing in a single community. As a pastime back-garden farming may catch on, but there must also be some substitute for the excitements of village life. Children must be schooled, and after leaving school employed—perhaps in village crafts—if hooliganism is to be averted. Here is town-planning with a vengeance. The Colonial Medical Service's resources in personnel are already fully stretched; so the scheme must from the start be medically independent. The organisers, likening their undertaking to a military operation, are seeking to benefit by the Army's campaigning experience. Hospital and field medical equipment are to be of standard Army pattern, and a R.A.M.C. officer has been seconded as chief health officer, to be joined probably by an Army hygiene officer.

For Africa one virtue of the scheme is its flexibility: it can be scaled up or down as needs dictate, and the developed land may be used for other cereals and even for animal husbandry. Among the other likely benefits are a strengthened economy; improvements in water-supplies and in road, rail, and port facilities; the fruits of research into such fields as meteorology, soil fertility, and crop diseases; and the disappearance, through bush-clearing, of the tsetse fly from large areas. The greatest indirect benefit will be the opportunity for the African to learn modern farming methods. Only one man is needed for every hundred acres, but of the 300 farming each 30,000-acre unit 70 must be taught to be technicians. About the need for an object lesson on these lines the surveyors are emphatic:

> "Some idea of agriculture in East and Central Africa can be gathered by imagining the deplorable state of production which would occur with farms in Britain if all straw and other crop residues were burnt, no manures of any kind were ever applied to the land, and a small hand-hoe was the only implement used in crop production. If we add to this a condition of malnutrition and such debilitating diseases as malaria and internal parasites, including hookworm, some idea may be formed of the conditions of crop production in tropical Africa."

Finally the scheme will provide much-needed living-space.

> "Excess of population," says the report, "could be accommodated on millions of acres of potentially good agricultural land which exist both in Tanganyika and Northern Rhodesia. But much of this is tsetse infested and densely covered with bush. There can be no hope for migrations of people into such land, so long as they have to depend on the axe and the handhoe to bring it into use. Only by means of the tractor and the bull-dozer, the ripper and the disc-plough can such land be brought into a state fit for permanent human habitation."

These are the methods now being called into use. For once, it seems, good business may go hand in hand with sound colonial development.

JOINT CHANGES IN CANCER OF THE LUNG

JOINT changes are occasionally recognised in cases of pulmonary carcinoma and other lung tumours, and they may even be the earliest feature which brings the patient to the doctor. Complete examination then reveals an unexpected radiological opacity which represents a neoplasm of the lung. This tumour may be symptomless, and on first sight it may seem difficult to establish any connexion between lung and joint conditions. It is common to find in such cases that the joints have been treated as rheumatic without benefit. They are characterised by a polyarthritis affecting principally wrists, fingers, and ankles—less often elbows, knees, and spine. There is considerable swelling of soft tissues, and bone changes typical of hypertrophic pulmonary osteo-arthropathy are seen in advanced cases. Clubbing of the fingers is common and takes the drumstick form. Pain is a constant and distressing feature, associated with severe limitation of movement. There appears to be little relationship between the site and size of the lung tumour and the severity of the joint lesions.

The arthropathy may be dramatically relieved on removal of the lung. Patients who were so crippled that it was difficult to place them on the operating-table have claimed loss of pain and improvement in joint movement on their recovery from anæsthesia after pneumonectomy.

---

[1] A Plan for the Mechanized Production of Ground-nuts in East and Central Africa. Cmd. 7030. H.M. Stationery Office. Pp. 48. 1s.

Some have been walking about comfortably a week or so afterwards, and though structural changes persist the swelling of soft tissues may resolve.

Three cases which fall into this category are reported from Argentina by Rottjer and colleagues.[1] In their patients, whose ages were 44, 47, and 64, pneumonectomy was performed with sudden relief of the "rheumatic manifestations." The tumours were classed as adenocarcinomata, but they do not say whether there was the extensive tissue breakdown or infection which is usually seen in this type of case. No satisfactory explanation of the association of joint and lung conditions has been forthcoming. Anoxia can hardly be the link, since improvement results from excision of the affected lung. Theories based on dyspituitarism and endocrine disturbances have been advanced, but more attention should be given to sepsis from breakdown of the growth. The syndrome can only be regarded as an occasional occurrence, but it deserves more detailed investigation and should be borne in mind as a possible pointer to early diagnosis.

THE SPRINGS OF DELINQUENCY

STUDIES of criminal psychology have important bearings on juvenile delinquency and on remedial methods in punishment. The Institute for the Scientific Treatment of Delinquency was established fifteen years ago, after the Medical Research Council had shown that scientific methods of diagnosis and treatment could be applied to people serving prison sentences. A letter from the Archbishop of Canterbury, Lord Horder, Sir Cyril Burt, Mr. J. A. F. Fergus, and Dr. Edward Glover, in the *Times* of March 12, tells the present need of the institute for support. During the war it undertook many clinical studies of delinquent and antisocial disorders, and much successful treatment. The recent crime in an approved school, where the violent fantasies of adolescence found outlet in actual murder, illustrates the need to continue and expand such studies. The crime, horrifying as it is, reveals so little grasp of reality or of ability to picture consequences, such hunger for notoriety at any cost, and such disregard for the sufferings of others that it is a symptom of very grave disorders in the children who committed it. If we are to prevent similar disasters we must find methods of training delinquents more effective than our present ones. The institute exists to forward such studies, and many interested in juvenile delinquency will wish to give it their support. The address is 8, Bourdon Street, London, W.1.

PLASTIC EYES

THE acrylic resins, used for some time in dentistry, have proved satisfactory for making artificial eyes. Plastic eyes are unbreakable and can be added to or subtracted from if the socket changes in shape. It is also claimed that the constant action of the tears does not roughen their surface and necessitate a change of eye every 1 or 2 years, as happens with glass; but the eyes have not been long enough in use for anyone to make dogmatic statements about their lasting powers. In difficult sockets an impression of the socket can be taken with 'Negocoll,' which is just solid at body temperature and liquefies on further slight warming, the plastic eye being then shaped from this mould. The iris is painted on paper and incorporated in the eye behind a layer of clear resin.

These eyes are somewhat heavier than glass ones, but no other disadvantage has become apparent except the price, which must be reduced before they can hope to become popular. The cost is now five times that of a glass eye, and there seems no reason why this should be so. The skill required to blow a glass eye must surely be greater than that needed to make one in plastics.

The acrylic eye has been adopted by the American Veterans Administration for all ex-Servicemen who require artificial eyes, and no complaints have so far arisen.

CONTROL OF ANTIBIOTICS

THE Penicillin Bill, presented in the House of Lords on March 5 by Lord Listowel, makes it an offence to sell or supply penicillin (or similar substances included by regulations) to the public except by or under the direction of a doctor, dentist, or veterinary surgeon, or by a chemist on the prescription of a doctor, dentist, or veterinary surgeon. The Government's advisers think that free access to penicillin would be dangerous to the public health, and for this reason it has been decided to continue the measures of control made under the Defence Regulations by the Minister of Supply, even though there is now enough penicillin for all home purposes and a surplus for export.[1] The main danger is thought to be that indiscriminate and inadequate dosage might lead to the production of insensitive organisms. Penicillin might also be used for the self-treatment of venereal diseases, which would add greatly to the difficulty of preventing their spread.

The Bill applies only to the supply of penicillin to the public. It does not impose any controls on wholesale dealings or exports. Power is given to the Health Ministers to make regulations bringing under the same control any "other anti-microbial organic substances produced by living organisms," after consultation with the Medical Research Council.

STAFF SHORTAGE IN MENTAL HOSPITALS

THE murder of a patient in the Oxford County and City Mental Hospital last November, which was described at an inquest on March 3, was a dreadful result of the lack of nursing staff. The ward in which the murder was committed contained 91 patients, and only one nurse was on duty at the time. Two other patients were in the habit of helping the nurse in the mornings, and they were washing the murdered patient in the bathroom at 6.30 A.M. on the day in question. According to their evidence, they afterwards carried her back to bed, but the nurse testified that when she visited her at 7 A.M. she was dead, having been strangled. The verdict was of murder against some person unknown.

These dangerous staff shortages must not be allowed to go on. The mental hospitals should at once start considering the employment of part-time nurses on terms similar to those which have proved successful in institutions for the chronic sick. The mental subcommittee of the Rushcliffe Committee have already recommended scales of pay for such nurses, which the Minister of Health has approved.[2] For nurses working less than 30 hours a week they are: ward sister 3*s*. an hour, deputy sister 2*s*. 6*d*., staff nurse 2*s*. 3*d*., nursing assistant (class I) 2*s*., temporary war emergency nurse 1*s*. 10*d*.

LORD HORDER, who is chairman of the Standing Committee on Nutrition of Food and Agriculture Organisation of the United Nations, left for Washington on March 15 and will be away until April 14.

THE first scholarship for the British Empire Nurses' War Memorial Fund has been given by the Royal College of Physicians of London. Lord Moran, in announcing the gift, spoke of the nurses as colleagues to whom doctors owe everything: "it would be impossible for us to work without them." The sum of £200 a year for seven years has been given under covenant, which will bring in the necessary £350–375 for this travelling scholarship. A second scholarship has been given on similar terms by Viscountess Mountbatten.

Reconstruction

GENERAL PRACTICE TOMORROW

H. H. Leeson
M.C., M.R.C.S.

Regulations and terms of service for general practitioners under the National Health Service Act must soon be made. General practitioners are the shock troops of medicine—on whose skill, decision, and courage the whole service will stand or fall—and the new arrangements must be such that the finest type of men will want to undertake the work. What then will attract the best type into this branch of medicine? Here in brief is what we want:

Reasonable working hours.
Suitable premises to work in, with ready facilities for all forms of simple examination.
Relief from clerical duties other than patients' case-taking.
Reasonable holidays each year, and relief if sickness overtakes us.
A service in which we can practise our craft without having to build up a business connexion—one in which other doctors can be colleagues, not rivals.
Opportunities for study and refresher courses when necessary.
A living wage on qualification with prospects of making a good income, according to ability, by the age of 40 (or less).
A pension on which to retire in comfort in our old age.

REASONABLE WORKING HOURS

Most general practitioners begin their day about 9 A.M., with morning surgery, and thenceforward are more or less busily engaged till tea-time at 4.30-5 P.M. Then comes evening surgery, which may end at any time from 6.30 onwards according to the district. Most people would call this a good day's work, but the practitioner's day seldom ends there. The evening rarely passes without further calls, and when these have been attended to he may still be called out after he has gone to bed. This goes on week in, week out—Sundays and half-days excepted, unless an emergency arises. No-one could describe this life as "reasonable working hours." No wonder there will be a rush for specialist jobs.

What then should be considered a reasonable day for a general practitioner? Of course, he will have to hold morning surgery as usual, and also evening surgery as usual, and pay such visits during the day as are required; but once evening surgery is over he should be free of all duties until 9 A.M. next day. He should also be entitled to a half-day once a week and to a whole day off on Sunday. During his absence from duty the work must be taken over by an emergency officer. Easy to arrange when the health centres are started.

These proposals might at first meet with criticism from the public; but opposition should be dispelled when it is explained that doctors, like others, get tired, and that when tired their brains may become clouded and their judgment warped, with consequent risk of mistakes.

SUITABLE PREMISES

How many doctors have suitable premises to work in? The average general practitioner cannot afford the substantial sum needed for good accommodation and equipment. It is not his fault that he has not got the place he would like. What he wants in order to provide a better service is free and rapid access to a first-class X-ray and laboratory service: the swab, the blood-count, the hæmoglobin estimation, and the X ray have now become indispensable.

CLERICAL WORK

Those of us who are fortunate enough to employ a secretary or book-keeper dispenser know how much they can relieve the busy doctor of clerical work. With the advent of health centres most of this non-professional labour will disappear, the general practitioner being responsible for his own case-takings only. All record-keeping, forms, and returns should be tackled by the clerical staff under the lay superintendent.

REASONABLE HOLIDAYS

A month's holiday each year is essential to any brain-worker whose work is as long and arduous as that of a general practitioner. It need not be taken all at once. Yet not many of us get it—principally, I believe, because of the expense. To begin with, thirty days' locum fees at £2 per day=£60. Then the house has to be run, and food, &c., provided; on top of which comes a month away, probably for four, at some hotel or farmhouse. £100 goes nowhere.

Under a national service, properly run, the picture should be very different. The locum is provided; the health centre goes on; and there are holidays with pay. The only expense to the doctor would be the cost of his family by the sea or in the country. *In comparable forms* of Government service at least a month's holiday with pay is allowed. Why not for the general practitioner?

COMPETITION OR COÖPERATION?

The time is long past when doctors should be forced to look on patients as a means to an end. Here I cannot do better than quote the Spens report:

> "The help, support and comfort that a doctor can give to his patient must, in our judgment, be seriously affected if a doctor is himself seriously worried. . . . We have no doubt that low incomes have in fact been a source of great worry to many general practitioners and prejudiced their efficiency. If, therefore, we are to attract the finest type of man into the profession, we must ensure that he is able to look on each patient as a case and not as a source of income."

I am sure all of us who have been in the public service—*in Army, Navy, or Air Force, or in municipal life*—must have appreciated, as I did, the delightful spirit of camaraderie, and the mutual assistance and coöperation that existed there. In the late war, when many general practitioners worked under my administration, I was much impressed by the speed with which they acquired esprit-de-corps and their liking for it compared with the competitive and soul-breaking methods of civil life.

OPPORTUNITIES FOR STUDY

The science and art of medicine move so fast these days that it is difficult for even the most successful general practitioners to keep themselves up to date; yet all should be cognisant of the latest forms of treatment. Not very long ago, in a remote country district, an elderly practitioner told me that his initial dose of the sulphonamide group of drugs was one tablet three times a day; yet his patients thought a lot of him. A compulsory refresher course every three years should be provided without expense *to* the doctor, and should be followed by a rise in pay.

REMUNERATION

And now I come to the most controversial part of my article. What remuneration should a doctor receive in a publicly organised service and how should it be computed?

It is obvious that a young man or woman, on entering the service, must have something to live on; and this should be the basis on which all future emoluments are built up. The Spens Committee very rightly recommended for assistants a salary on entry of £500 per annum. If this were regarded as the basic salary for all doctors, it could then be supplemented according to age, length of service, ability, position held, and number of patients for whom responsibility is taken.

On this plan remuneration would fall under the following heads:

Basic salary.
Increments for length of service.
Capitation fee.
Administrative, specialist, or extra-duty pay.
Locality allowance.
Mileage allowance.

Every doctor would draw the basic salary of £500. In addition he would receive, say, £25 per annum for each year of service, and capitation fees according to the number of patients on his list. Doctors undertaking administrative or specialist work, or extra duties, would be paid according to the particular post held, and their income therefrom would take the place of the capitation fees paid to the general practitioner. A locality allowance would be given to doctors working in unattractive or congested or less healthy areas, and a mileage allowance to rural practitioners who, owing to distance, cannot look after as many patients as their urban counterparts. Finally, a higher capitation fee might be paid in respect of patients over 60 years of age, so as to compensate doctors working in places where there are many elderly people demanding more than normal attention.

The number of years a practitioner has already spent in practice should be allowed to count for seniority in the new service: thus a doctor of ten years' standing would enter with ten years' seniority for pay and other purposes. I have suggested elsewhere [1] that a practitioner of more than ten years' standing should be graded as a specialist in general practice.

PENSIONS AND SUPERANNUATION

General practitioners as a class are not well-to-do; in fact lack of means often obliges them to go on working long after the usual retiring age. On the institution of the new service some elderly doctors may find themselves in a somewhat parlous position: in these difficult years they may have saved little or no money, and the compensation paid by the State for the goodwill of their practices will not suffice to keep them. These men will be ineligible for a pension in the ordinary way, yet it will be in the interest of the community that some of them should now retire. How is it to be done?

I suggest that (save in exceptional circumstances) all practitioners who join the service on its formation and are 65 years of age or over shall be given the option of (*a*) *receiving a cash settlement for their practices*, or (*b*) forfeiting their right to a lump sum, receiving in lieu a pension for their lifetime. On this plan a practitioner whose financial position is sound could augment his capital by accepting a lump sum, while one whose resources are poor would be able to choose a pension instead.

What should this pension be? The ordinary Civil Service scale of $^1/_{80}$ of retiring salary for every year of completed service would not be applicable unless amended. If, however, this small body of men were allowed to reckon the number of years since qualification as years of service, then in most cases they would get $^{40}/_{80}$ of income on retirement, which should meet their needs in their old age. For this class of man some sort of "means test" might have to be devised, in which the applicant would be required to prove that in his case the concession was necessary.

CONCLUSION

After many conversations with all grades of medical men—young and old; consultant, specialist, or general practitioner—I am certain that the success or failure of the National Health Service will depend in the first place on the terms and conditions offered. Let us therefore profit by the lessons of the past. *No ship ever sailed well yet with a discontented crew.*

Special Articles

LACTATION

A POSTGRADUATE LECTURE

In his lecture to postgraduates at the Royal College of Obstetricians and Gynæcologists on Jan. 10 Mr. S. J. FOLLEY, D.SC., *of the National Institute for Research in Dairying, Reading, discussed recent researches into the physiology of the mammary gland which are likely to have clinical applications.*

Earlier work indicated that œstrogen mainly stimulates the growth of the mammary ducts, while progesterone is particularly related to lobule-alveolar development. Species differences in the mammary growth response to œstrogen have however been recognised. In species such as the rat, œstrogen causes very little alveolar growth; in guineapigs, ruminants, and probably monkeys, considerable (though not necessarily normal) alveolar as well as duct development results from treatment with œstrogen alone. In the ruminant these findings may be of practical importance in connexion with the artificial induction of udder development and lactation in barren animals. On one view ovarian hormones do not directly cause mammary growth but do so indirectly by stimulating the secretion by the anterior pituitary of two specific mammogenic hormones which are the direct agents promoting growth of the mammary ducts and of the alveoli. While the integrity of the anterior pituitary does seem to be necessary for normal mammary growth under experimental conditions, the truth of this "mammogen" theory has not yet been proved with certainty.

Modern studies on the function of the mammary gland date from the discovery in 1928 that the anterior pituitary is concerned in the initiation of lactation (lactogenesis). This work was the first of numerous studies which have culminated in the preparation, as a pure protein, of an *anterior-pituitary hormone, prolactin*, which is widely regarded as a specific lactogenic hormone solely responsible for lactogenesis. However, it appears probable that other anterior-pituitary hormones are also concerned in the initiation of lactation, so we are led to the conception of a lactogenic hormone complex. Prolactin is less effective than crude anterior-lobe extracts in stimulating already established lactation (galactopoiesis), and here again a hormone complex, which may or may not be identical with the lactogenic hormone complex, is probably involved. This explains the variable and sometimes disappointing results obtained in clinical trials of prolactin for the treatment of hypogalactia, since the preparations used are standardised only in terms of prolactin by the *pigeon crop-gland method*.

Experiments on small animals had led to the view that œstrogen inhibits lactation, a view which has been accepted and applied in practice by many clinicians. The reality of the inhibitory action of œstrogen has however been questioned, and some clinicians ascribe the beneficial effects of œstrogen in cases where lactation is contra-indicated to the relief of painful breast engorgement. The fact that œstrogen under some conditions exerts mammogenic and galactopoietic effects is illustrated by recent work on the artificial induction of udder growth and lactation in virgin goats and heifers.

The posterior pituitary is now thought to be concerned not with the secretion of milk but with the mechanism governing its egress from the mammary gland—in other words, with the process of suckling or milking. When a cow is milked, palpation of the teats or the operation of any other conditioned stimulus is quickly followed by a sudden rise in milk pressure in the udder cisterns—the so-called "let-down"—only after the occurrence of which can the correct yield be obtained. The let-down has been ascribed to a nervous reflex causing contraction of smooth muscle-cells associated with the alveoli, or alternatively causing "erection" of the udder tissues due to occlusion of venous vessels and the engorgement of a corpus cavernosum with blood. According to a recent view, the let-down results from the contraction of smooth muscle-cells associated with the alveoli under the influence of oxytocin reflexly secreted by the posterior lobe of the pituitary in response to the stimuli of milking.

The research done on the physiology of milking throws light on some of the difficulties encountered in infant-feeding, since a failure of the discharge mechanism will amount to a failure of lactation, and many cases of deficient lactation in women may be due not to secretory deficiencies but rather to a breakdown of the neuro-hormonal mechanism governing the discharge of milk from the mammary gland.

MICROFILM PROJECTORS

A CORRESPONDENT remarks that the microfilm projectors now available are, in general, adaptations of models originally designed for reading newspapers measuring about 18×24 inches, and radical changes in their design will have to be made if they are to be used for books and journals whose pages seldom measure more than 9×12 inches. He sends us the following suggestions for the design of a microfilm projector suitable for use in a medical library.

To be acceptable to the student (undergraduate or postgraduate) the projected image must be presented under conditions comparable to those under which he reads his book: it must be in front of him, inclined at an angle approximately normal to his line of vision, and so placed as to permit a notebook to be near at hand which is properly lit for comfortable writing but not much brighter or dimmer than the projected image. The viewing surface must be screened from the general room lighting, for otherwise the projected image would be diluted, and being low in contrast would be difficult to read.

One of the chief objections to microfilm is that, being a continuous strip, it is awkward to refer from one "page" to another some distance away. In fact, with existing apparatus, it is tedious to read a long text which refers over a number of pages to, for example, a diagram or chart which was printed on the page on which it was first needed. For this reason the projector should provide a mechanical means of transferring rapidly and easily from one section of the microfilm to another either forwards or backwards, and it may be desirable to make this mechanism foot-controlled.

A useful addition would be a numbered counter or dial which, when set initially to the page number, will change automatically as the pages pass through the projector. This is important in cross-referring, for as the "pages" flash through their numbers are illegible, and much time would be wasted and annoyance caused by continually stopping to find which page is now in the field; a counter will remain legible and can be followed all the time.

It is sensible to make the microfilm in such a way that, no matter what the size of the book, it appears a constant size on the microfilm; therefore the projected image, to be read comfortably, must be at least as big as the largest size of page customarily used, yet not much bigger or the angle of ocular scanning will be larger, and eye-fatigue set in rapidly. This is an important consideration which is closely allied with the contrast of the projected image, for if these two factors are neglected microfilm reading becomes tedious. But since different books are printed in different type-sizes variable magnification is desirable, ranging over ×6 to ×10.

A microfilm reader designed to satisfy the foregoing subjective requirements will also have to possess the following features.

Optics.—The optical train must be of first-class design, casting a clear, sharp, contrasty image, and be well ventilated. It should consist of a pre-focus compact-source lamp, backed by a mirror and facing an achromatic condenser system of sufficient diameter; the lens should be an anastigmat in a focusing mount. The film gate should consist of a plane-parallel glass pressure-plate bearing on a metal aperture. The entire optical system must be capable of being easily dismantled for cleaning, and so constructed that elements can be replaced only in their correct positions. The intensity of the light-source must be controllable.

Film Transport.—The pressure-plate must rise automatically before any film transport occurs, and fall back automatically when the film is stationary. It must be automatic, in that the film will come to rest with a "page" exactly in position over the gate, and not in any intermediate position. This transport can be electric, so that pressure on one button will cause the film to advance continuously until the desired page is nearly reached, and then under stabbing pressure will advance one page at a time, while pressure on another button will cause the film to run backwards similarly. As mentioned previously, these buttons may be foot-controlled. An alternative system can be devised which, looking like a 3-bank typewriter in which each tier is numbered 0–9, will permit the exact page desired to be automatically presented by prodding the appropriate keys: or a telephone dial system can be used. It is evident from these proposals that the mechanism is activated by motor rather than by hand.

Loading.—The projector must take both short lengths (6 inch) and long rolls (of up to 100 ft.) of film. The sprockets should engage smoothly and positively and the counter must be capable of being set initially to the page number in the gate and then remaining automatically in step. It would be desirable for the gate to accept both loose rolls and permanently maintained cassettes.

Construction.—The microfilm reader so designed would be a library model, made for hard and constant wear. It must be rigidly and soundly constructed, with fool-proof loading and working mechanisms capable of being easily serviced or replaced.

But this is only one opinion. It seems reasonable to ask, say, five men who use microfilm occasionally to try the best existing types of apparatus and then to draw up their own list of requirements. (They must be *occasional* users, for regular users will have become accustomed to the characteristics of a given model, and one can get used to anything with practice.) With these desiderata for guidance, manufacturers might abandon their present production of ad-hoc adaptations of apparatus originally made for other purposes, and produce a microfilm projector designed from the start for the medical library.

B.C.G. IN SCANDINAVIA

A LARGE part of *Nordisk Medisin* for Jan. 10 is devoted to several papers on B.C.G. by representatives of the four Scandinavian countries.

In Denmark B.C.G. vaccinations enjoy such a vogue that they are numbered by the ten thousand, and in the island of Bornholm more than 22% of the whole population had undergone such vaccination by 1945. One of the Danish targets at the present time is to vaccinate with B.C.G. every tuberculin-negative child at the school-leaving age, and to catch all the older tuberculin-negative persons as they present themselves for admission to higher schools, universities, and fighting services. In Norway Dr. J. Heimbeck continues to pursue the careers of his B.C.G.-treated nurses as they grow older and older and are more and more difficult to trace. In Sweden type-determinations of the tubercle bacilli found in the rare cases developing tuberculosis after B.C.G. vaccination have yielded the reassuring information that these bacilli were of the *human* type—i.e., not to be identified with bovine-type B.C.G. At present every B.C.G. vaccination is a notifiable operation in Sweden, and it is hoped that even after this precaution has been shelved, reliable data will continue to be recorded with regard to the total number of vaccinations and the incidence of tuberculosis after vaccination. In Finland, as in the other three Scandinavian countries, experiences with B.C.G. are encouraging despite the fact that the B.C.G. vaccinations in the Finnish army were carried out during the war under extraordinary difficulties.

BOOKS FOR BRITISH MUSEUM

DURING the blitz the library of the British Museum lost 200,000 of its 19th- and early 20th-century textbooks. In medicine the specialties which suffered most were specific diseases of the various organs, midwifery, mental diseases and psychiatry, and climatic treatment (including books dealing with spas and the Swiss and Mediterranean resorts). Though many of these books are no longer of any great value in themselves, copies should be kept on record in the national library, and Mr. A. F. Johnstone-Wilson, the assistant keeper, would be grateful for any help which doctors can give him. He should be addressed at the department of printed books, British Museum, London, W.C.1.

In England Now

A Running Commentary by Peripatetic Correspondents

In the nurseryman's seed catalogue I was a bit startled to see under the heading "Herbs" not only sage, thyme, marjoram, and such like but belladonna and henbane. In imagination I saw the enthusiastic amateur, resolved on a herb garden to provide varied seasoning for monotonous dishes, planting a packet of every herb listed. Being indigenous plants, belladonna and henbane should grow from seed much more readily than sage or parsley. Any medical student will show you the shiny black berries of deadly nightshade in the woods and perhaps even the hairy leaves of hyoscyamus niger.

Cooks are not very discriminating. When the recipe tells her to put "a bunch of herbs" in soup or stew she will naturally pick a piece of every herb available. One cook I had boiled Michaelmas daisy leaves instead of spinach; they looked and smelt quite like spinach in the pot, but some intuition led me to ask her to show me the plant from which she had gathered the leaves. An Irish cook I had ignored the garden mint and made sauce of a wild, hairy variety growing in a waste corner of the garden; it tasted unusual but was harmless. Another Irish girl sliced, fried, and ate some hyacinth bulbs, under the impression that they were onions.

So I wrote a friendly note to the firm when I ordered my seeds, asking if it was not rather risky to include poisonous plants among herbs. They replied that the classification was "herbs" and not "culinary herbs" and that those for domestic use were starred. The demand for henbane and belladonna was so great, they said, that it seemed simplest to catalogue the seeds in this way, and they enclosed the labels of the seed packets in question which bore a warning note that these plants are dangerous and highly poisonous.

I suppose it is all right. But in a country where dangerous drugs seem to be constantly left in cars, dropped in the street, or used to flavour the icing of Christmas cakes one doubts whether poison labels get the respect they deserve.

When Adam delved and Eve span,
Who was the committee-man?
Surely the answer's plain as day—
Coiled beneath the tree he lay,
Waiting till man at last should reach
The doubtful faculty of speech,
And two, though company, should note
A third can give a casting vote.
Who else in Eden would incite
The first debate on wrong and right,
Or advocate as human food
Knowledge of evil and of good?
From which original mistake
No-one profited save the Snake,
Who watched, though source of all our woe,
Our proletarian parents go
To toil outside that Paradise
Where self-communing still he lies.

W. R. B.

* * *

Running commentary, or cautionary tale? I don't know. Perhaps both. During the Great Frost I had to drive 50 miles for a check-up on my resected colon. Despite a blizzard from the east, the outward journey was uneventful. The first note of warning was sounded when the radiographer invited me to strip and put on a dressing-gown. Shivering, I extended myself on the metal couch and a cold nozzle was introduced. A long pause; then the radiologist appeared, muttering, "Let's hope there won't be a cut. It plays Old Harry with the exposure." His assistant released the forefront of the barium enema and an icy sensation in the rectum made me gasp, but my colon was made of sterner stuff and clamped down firmly on the intruder. Much time passed, but after adjurations to "give it all you have," man triumphed over Nature, and a Zeppelin-like shadow appeared on the screen. An invitation to get rid of this in an adjoining apartment was hastily accepted, but subsequent screening revealed "a normal pool in the cæcum."

After a cup of tea had lulled my lower bowel into a deceptive tranquillity, I began the homeward journey. The blizzard mounted, and even in a heavy overcoat my teeth chattered and my hands and feet grew numb. At the 30th milestone the "normal pool" suddenly became highly abnormal. The only possible refuge was a railway culvert facing east. Huddling under its indifferent shelter, hasty preparations were made, when, as by magic, a female form on a bicycle rapidly appeared. A mad plunge into the heavy snow of an open field beyond, and catastrophe was just averted. As I brushed most of the snow from the inmost recesses, and regained the car, I fully determined to advise my patients that train was better than car on such excursions.

* * *

Rather incongruously the Sage was smoking a churchwarden and listening to the Children's Hour when I paid my last weekly visit to inquire about his pernicious hypermetropia. He switched off.

"I like hearing the B.B.C. trying to romanticise the Stuarts," he said. "D'you remember that bit in Pepys about Charles II and his naked women?" "Anyway I prefer them to the Tudors," I answered, remembering all I owe to Haig and Haig, Dewar, and the rest. "The Tudors had their uses. It has always been the function of Welshmen, people who can take a detached, outside view of our codes, to break up the established ways of the dominant Anglo-Scotch. Henry Tudor's son nationalised the Church and monasteries, rather selfishly perhaps; Cromwell, who was half Welsh, tried to nationalise everything; then in our time Lloyd George nationalised insurance; and now we have your Mr. Bevan." "*My* Mr. Bevan!" I snorted, but refused to be drawn further.

"You old men are all the same," said the Sage. "Where do you think this comes from?" He picked up a newspaper cutting and holding it at arms-length read:

> ". . . in his Bill he was content with an antiquated notion of medicine and of medical service; he took for granted without inquiry a notion built of some vague knowledge of village clubs and the old-fashioned *vade-mecum* way of doctoring. . . . Gloss it as we may, contract practice will stand lower in public esteem and will be of lower average efficiency and much less humane; it will damp the aspirations and blot the high-minded ideals with which I, who know, say the young physicians of today are entering our profession; it will push them back to old-fashioned routine and to ill-remunerated and therefore undervalued services."

"Guy Dain?" I guessed. "No. Clifford Allbutt in the *Times* of Jan. 3, 1912." "Damn your eyes," I said.

* * *

Cautionary Tale.—During the war children's physicians often found themselves *called on to* help with adult wards. This is a necessary preamble to the following case-history.

A girl of ten years was sent to the children's outpatient department because of a curious loss of power in her limbs with inability to walk. It was obviously of psychological origin. The background was of a broken home: father had left mother about five years before, the child and her mother had been living with grandparents and various uncles and aunts and cousins. Suggestions about reconciliation and getting back to a normal home life were not well received. Child-guidance was arranged, but the child meanwhile got worse, refusing even to get out of bed, and it was thought that a period in hospital might help. The day she was due for admission happened to be the day of the outpatient clinic. I was told that her father wished to see me and when he came in he seemed to have a familiar face. He remarked that he thoroughly approved of my suggestions and was sure I could help his daughter because I had helped him so much!

It was not long before I had him placed in my memory. He had had a particularly objectionable peptic ulcer, liable to bleed at intervals and not responding to treatment. I had been asked to see him at our base hospital by a surgical colleague because, despite operative treatment, he was still full of symptoms. My inquiries had pointed clearly to domiciliary unhappiness and I had strongly advised him to leave a nagging wife. He had had five years of complete absence of symptoms; but was I responsible for his daughter's psychosomatic disorders?

Letters to the Editor

THE STUDENT NURSE

SIR,—It is grievous to think that the efforts of Dr. Russell Brain to obtain some amelioration in the teaching of medicine to nurses met with no support in the General Nursing Council. Those who failed to appreciate the importance of his proposal can have had little practical experience either of teaching medicine to nurses or of the examination itself.

Speaking as a teacher and examiner of some experience, I am convinced that the curriculum as established leads to the teaching of too much medicine with an infinity of useless details: many of these nursing trainees cannot possibly absorb what is placed before them, but their efforts lead to an appalling mental muddle. The answers to the questions in the last paper on medicine provided many characteristic examples, of which a few are given. The train of thought in each case is easily followed.

"The characteristic point in the joint is the appearance of Aschoff's nodules, consisting of small blisters." (Acute Rheumatic Fever.)

"The Basal Systolic Rate is carried out each week." (Idem.)

"Chloral Hydrate is present in the blood, and patients suffering from anæmia suffer from loss of it."

"In uræmia acetone nodules can be detected on the skin like beads."

"The child may be born without a mouth or nose." (Congenital Syphilis.)

"Has no accommodation of the pupils to light." (Idem.)

"Mumps is an enlargement of the Parathoid glands. Treatment, exercises of the lower jaw, as chewing some apple."

The first reaction on reading such replies is to smile; this is followed by admiration for a gallant, if ineffectual effort of memory, succeeded in turn by fears as to the application of such imperfect knowledge in crises and the administration of drugs and, finally, by despair that schedules can be of such a calibre as to produce such answers.

The need for nurses is great, and calls for every effort to eliminate wastage. A reconditioning of the syllabus and examination should be one of the first steps of the General Nursing Council to meet the need.

Lastly, it is up to all of us, teachers and examiners, to take to heart those last dozen lines of your leader, "First Things First."

DOUGLAS FIRTH
King's College Hospital. Consulting Physician.

SIR,—In your issue of Feb. 1 it is suggested that student nurses should receive a maintenance allowance, say £100 per annum, at a flat rate during training. This would certainly be a step towards recognition of student status. The increment system is a relic of the housemaid's wages, so much a year, rising. But the exact figure to be paid would require most careful consideration, having regard to all the alternatives now open, and should be designed to attract the optimum number of suitable candidates.

Apart from the special case of students, it seems a matter for regret that the Rushcliffe Committees did not seize the opportunity to work out a scientific scale of salaries based on some system of points. Such a scheme could have taken into account advantages and disadvantages—risks, real or imaginary, distastefulness of the work, deficiency of amenities, &c. It might also have more justly assessed the relative contribution made by members of each branch of the service (e.g., by ward sisters).

The practice of computing salaries as a cash payment, plus a valuation of emoluments which actually vary in real value from hospital to hospital, has drawbacks. It prevents exact comparison between the position of student nurses and other categories of student or of entrants into commerce or industry. It has permitted an unfair valuation of emoluments, so that the nurse who does live out often finds herself trenching on her cash salary to provide the necessities of life. Moreover, had all salaries been paid on a cash basis, each nurse paying for her board and lodging, even if obliged to live in, I doubt if the discrepancy between the salaries of male and female nurses permitted in the Rushcliffe scale could have been condoned.

A later article (Feb. 8) put in a plea for separate finance for training school and hospital. Such separation of accounts and aims would be easier if training in each region were organised on a regional basis, only selected hospitals being allowed to take students, and these being required to offer a high standard of staffing and equipment. So long as hospitals are allowed to recruit students without reference to the needs of the service as a whole the practice of relying mainly on student labour is likely to continue, with its attendant evils of long-drawn-out training and wastage and spoiling of good material.

I think all nurses are greatly indebted to THE LANCET for its constant discussion of the problems connected with the reorganisation of the nursing services on which much of the success of the National Health Service must depend.

London, W.2. G. B. CARTER.

SIR,—I am in entire agreement with the argument and the conclusions of your correspondent of Feb. 8. May I, however, correct one misconception which may arise from the reference made to the Nightingale Training School at St. Thomas's Hospital?

Quoting from Worcester's book on *Nurses and Nursing*, your correspondent gives the impression that the Nightingale School is a separately endowed school, financially independent of the hospital. This is unfortunately not the case. Virginia Dunbar in her thesis *The Origin and Early Development of Two English Schools of Nursing*,[1] which was written during a year's study of original sources, deals specifically with this. Whereas, in 1864, when the school started, the Nightingale Fund undertook all the expenses of its fifteen students for one year, by 1867, when the number of students rose, the fund was unable to pay for their maintenance, and the additional students had to pay this themselves. By 1892 the hospital paid a deficit of £444 on the first year's maintenance of the "free" students, and after the first year accepted them all on the staff of the hospital for a further compulsory period of one or two years. By 1900 the hospital was also providing tuition during the second and third year of training, and today the position is very much the same. The Nightingale Fund now undertakes the tuition of probationers in their first year; but the training lasts four years, and the hospital is responsible for everything the fund does not pay.

The fund, raised as the nation's gift to Miss Nightingale in acknowledgment of her work in the Crimea, was £44,000, and this she put in trust for the Nightingale School and certain other activities connected with the training of nurses. I am not aware that any considerable additions have since been made to the fund, and from time to time the income has been applied to other activities within the ambit of the trust. The Nightingale School is not therefore a "well-endowed school," and in fact has almost lost its original independence. Its merit lay in its original conception and demonstration, but this conception has failed to gain acceptance in its country of origin.

OLIVE BAGGALLAY

London, W.1. International Foundation.

AN EXPERIMENTAL COMMUNITY

SIR,—Questions of medical administration are at present diverting attention from the proper scope of medical endeavour. In two short generations the advance of biological, social, and medical science has transformed the potential field of medical practice. In the welter of information there seems danger of losing our way.

In medical teaching it is a platitude that an understanding of physiology is the necessary condition of a proper insight into pathology. Now that biological science has shown the intimate interplay between living things and their environment, on the nutritional, personal, and social levels, there is need to reapply this old saw. We must now distinguish normal living function within environmental complexes from pathological function.

---

[1] This thesis in manuscript can be seen in the libraries of Bedford College for Women and the Royal College of Nursing where Miss Dunbar studied during her year as a scholar of the Florence Nightingale International Foundation.

With regard to the "gain" in antitoxic value—i.e., the ratio of the secondary response to the primary—it appears that the primary response was measured by Mr. Holt as an arithmetic mean by testing one pooled serum *from a number of animals.* The secondary response, however, was measured as the geometric mean of the values of a number of sera tested individually. The scatter of values after one injection is therefore unknown and may have been relatively great. In our view such a comparison is inadvisable, particularly as the smaller responses are usually subject to a greater scatter, thus providing a considerable divergence between the arithmetic and geometric means. Any conclusions as to so-called gain in antitoxin must take into account the following principles. An animal's response to a secondary stimulus depends on:

(1) The amount, nature, and antigenic efficiency of the stimulus.

(2) The degree of potential immunity reached by the animal at the time of injection.

(3) The amount of circulating antitoxin at the time of injection, in relation to (*a*) the combining-power and nature of the antigen and (*b*) the maximum response of which the animal is capable.

The fact that Mr. Holt finds there is an optimum concentration of aluminium for the production of good immunity is of great importance, and confirms and extends the observation of Miss Llewellyn Smith (1932) who found that the addition of Willstätter cream to a *sample of* A.P.T. *increased its antigenic efficiency.*

In the early days of A.P.T. the nodule formation and occasional sterile abscess produced by the carrier was much objected to, and on the basis of these objections we concentrated on producing A.P.T. with the minimum concentration of aluminium hydroxide consistent with a good depot effect. As far as can be judged in the absence of a common reference standard we have succeeded in producing A.P.T. of the same order of potency as those with large amounts of aluminium phosphate. It is possible that the "foreign-body" reaction produced by aluminium phosphate is less likely to lead to sterile abscesses than the reaction produced by aluminium hydroxide.

THE INTRAVENOUS DRIP

SIR,—Having initiated the popularity of the administration of continuous intravenous fluid by the drip method in this country 13 years ago, I have felt a grave responsibility at its widespread abuse. From almost the commencement, I urged that continuous intravenous fluid should never be given without keeping a properly recorded balance-sheet. Unhappily, I constantly find patients receiving the drips on the least provocation, but the balance-sheets are conspicuous by their absence.

The dangers of overloading the circulation because of well-meaning but unphysiological enthusiasm, short staffing, or forgetfulness, are so great that I am metaphorically hoarse from endeavouring to promulgate the gospel that "it is better to administer too little intravenous fluid than too much."

Professor Bentley's admirable pen-picture (March 15) of the dangers of abuse of a sovereign remedy will, I hope, attract great attention. The administration of parenteral fluid is largely in the hands of resident medical officers and house-surgeons, and I venture to think that if the instructions on p. 45 of the newly issued 15th ed. of *Pye's Surgical Handicraft* were adopted in every hospital, the abuse to which Professor Bentley refers would be reduced to vanishing-point.

Therapeutic pendulums are for ever swinging. Sometimes they swing too far, and become unhitched. The barber-surgeons overdid blood-letting, and a good remedy with definite indications became defunct. I fear that if Professor Bentley's injunctions are not heeded, a future generation may accuse us of having caused many deaths by drowning, and another excellent, nay, life-giving therapeutic procedure will pass into oblivion.

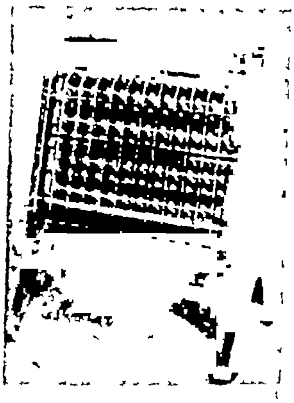
HAMILTON BAILEY.

London, W.1.

DEATH IN THE FIREPLACE

SIR,—In your leading article of Dec. 7, 1946, you urged the need for fireguards on electric and gas fires to protect the public—particularly children and old people—against the risk of clothes catching fire.

Fresh data have since come to hand which indicate the size of these risks. The Birmingham Accident Prevention Council, to whom the figures were submitted by the Birmingham coroner (Dr. Davison), inform me that during the past five years in Birmingham there have been 14 deaths from burning by electric fires and 6 by gas fires—20 in all. No exact data are yet available for non-fatal accidents of this kind, but such as we have indicate that they are to the fatal accidents about as 4 to 1. Taking the population of Birmingham (1,000,000) as a random sample of the 40 millions of England and Wales, we may conclude then that in the whole country during this five-year period these heating appliances have been associated with something like *800 fatal and 3000 non-fatal* accidents. The figures are, admittedly, not large in relation to the total number of such fires in use—and some of the accidents have certainly resulted from gross carelessness. On the other hand, there are grave reasons why we should not accept this accident-rate with complacency. It should be remembered that most of these injuries, even if not fatal (and many more recover now than was the case ten years ago), result in extensive scarring and often in impaired functional efficiency throughout the victims' lives. It is clear, too, that with the present coal shortage and the rapidly growing use of electric and gas fires (particularly of the mobile types) these accidents are likely to become more frequent. There is already evidence of such an increase.



Improvised grill guard fitted to standard electric fire.

These accidents could be prevented comparatively easily, and "if preventable why not prevented?" The case-histories of our patients show that their clothing usually caught fire because of a momentary contact of inflammable material with the heating elements—it would not have ignited if a suitable light guard had prevented this contact. The man in the street can easily satisfy himself on this point. He has only to hold a piece of inflammable clothing material (flannelette or winceyette) in front of an electric fire to find that at a distance of 1 inch or less it will burst into flame in a few seconds, whereas at 2–3 inches it can be held for more than two *minutes and still will usually not ignite.* A grill guard which keeps clothing at a distance of at least 2½ inches *from the fire will therefore prevent an accident in most* circumstances. (With gas fires the grill should stand away somewhat farther—not less than 3½ inches.)

Open coal fires are, it is true, responsible for considerably more accidents than electric and gas fires. (There were 61 deaths from coal-fire accidents in the Birmingham coroner's series for the past five years as compared with 20 for electric and gas fires.) Unfortunately it is much more difficult to secure protection against open fires. An efficient guard for these must be large and usually has to be removed for cooking and for stoking the fire. It also gets in the way in a small crowded room. In spite *of legislation in 1908 (Children and Young People's Act)* which made it an offence to be without a fireguard where there are young children in the dwelling, the Registrar-General's returns do not indicate that it had any decided effect on deaths from burns, and the Act has now become almost a dead letter. It would not be *feasible* to make the provision of a fixed guard compulsory on all new *open* fires, but such a provision could easily be insisted on in respect of electric and gas fires. A well-designed guard need detract little or nothing from the appearance of such fires and the additional cost would be small.

It is simple to improvise a grill guard for existing electric or gas fires. A cake-cooling tray or griller can be bought for a few pence at most ironmongers and easily wired to the bar or bars covering the elements (see figure). Failing this a piece of wire netting will serve, but care must be taken to ensure that the cut ends are turned in so that they cannot catch on clothing.

It has been suggested that such a fixed grill guard would considerably diminish the heating efficiency of electric and gas fires. Experiments suggest that this is not the case. At a distance of 26 inches from the fire illustrated, the rise in air temperature ten minutes after switching on was only 1° F lower with the guard in place, and at twenty minutes was only 2·5° lower. After that time the guard seemed to cause no further reduction.

Birmingham Accident Hospital. LEONARD COLEBROOK.

COMPRESSION OF MEDIAN NERVE IN CARPAL TUNNEL

SIR,—I was greatly interested in the article by Dr. Brain, Mr. Dickson Wright, and Dr. Wilkinson in your issue of March 8, but I am sorry that they do not mention the value of immobilisation of the wrist in both the diagnosis and treatment of this condition. The clinical picture of parasthæsiæ and impairment of sensation in the median-nerve distribution, plus wasting of the thenar eminence, usually following either a single injury or a period of overuse, is not an uncommon one.

The differential diagnosis from such conditions as the costoclavicular syndrome or lesions of the spinal cord may be very hard. A period of 3–4 weeks' immobilisation of the wrist will produce relief of the symptoms if these are due to compression of the median nerve in the carpal tunnel. I mention these points in case the recent article may lead to unjustified surgical onslaughts on the median nerve. If there is any doubt about the diagnosis of any pressure neuritis, it is wise only to operate when there has been relief with immobilisation and recurrence on activity. I have also wondered whether the apparent increase in frequency of the various types of pressure and friction neuritis is only due to one's being more aware of the syndromes, or whether there is a factor such as dietetic deficiency which is making the nerves more sensitive to trauma.

Liverpool. R. ROAF.

SIR,—I would like to point out an error in the first two illustrations to the article on compression of the median nerve in your issue of March 8. The transverse carpal ligament (flexor retinaculum) is represented as terminating distally at the distal skin crease, whereas this actually is its superior border. In the position represented, the nerve would be compressed, if at all, against the radius.

King's College, London, W.C.2. DAVID ADDERLEY.

SIR,—The article by Dr. Brain, Mr. Dickson Wright, and Dr. Wilkinson calls for comment.

First, the structure shown in fig. 1 as the anterior carpal ligament does not correspond in site, size, shape, or slope to any structure in the human body. Secondly, every reputable textbook of anatomy for the last 140 years at least describes the median nerve at the wrist as normally possessing those outward appearances of enlargement, pinkish coloration, and surrounding cellular tissue which your contributors regard as abnormal.

> *Cloquet* (1816)—" It passes . . . under the annular ligament of the carpus, adheres to them (the tendons) by a very delicate membranous cellular tissue, becomes thicker and broader than it was before."
>
> *Quain* (1837).—" Somewhat enlarged, and slightly reddish in colour . . ."
>
> *Piersol* (1906).—". . . it spreads out into a reddish gangliform swelling."

May I add the following notes ?

1. The arteria comes of the median nerve supplies the lower two-thirds of the nerve in the forearm. It is often somewhat enlarged and is regarded by some anatomists as the main primitive artery of the limb.

2. The anterior carpal ligament maintains the transverse arch of the hand, which is exaggerated in flexion, diminished in extension. The carpal tunnel is more circular and larger in flexion ; smaller and more flattened in extension.

3. Wasting of the thenar, hypothenar, and interosseous muscles is a normal feature of old age. The hand tends more and more to assume Hilton's position of rest with slight ulnar adduction.

4. The fibrocartilaginous ligaments of the metacarpophalangeal joints tend to show chronic thickening with limitation of the movements of the joints with (*a*) old age, (*b*) the menopause, (*c*) leucorrhœa, pyorrhœa, and gonorrhœa, and (*d*) heavy manual work, including domestic work such as scrubbing and ironing.

5. The number of sesamoids which ossify often increases in number and size as part of this general process of ageing.

6. Pins-and-needles and varying degrees of acroparæsthesia are common in working women, for vasomotor disturbances are more common in women than in men (cf. Raynaud's disease).

7. These patients would possibly have done just as well had the hand been tied up loosely over a golf-ball, tangerine, or other rare object with a view to resting the part.

8. Intermittent heavy muscular work, such as in fine-weather gardening, easily produces this " syndrome " in men over middle age, particularly if the handle of the working tool is of the wrong dimensions.

9. The baby does not learn to oppose the thumb until he is about 6 months old. It is not surprising that this movement should be one of the first to be lost in any process of " wear and tear " ageing.

10. Lastly, no clinician should regard anything in the body as abnormal unless it has been submitted to that acid test of anatomical accuracy and precision—Quain's *Textbook of Anatomy*.

Anatomy School, University of Cambridge. H. A. HARRIS.

⁂ We have shown Professor Harris's letter to Mr. Dickson Wright, who replies as follows : " In our diagram the artist certainly placed the anterior carpal ligament too high ; but no-one will suffer from this, because it emphasises the point which was felt important —namely, that the median nerve swelling extended two inches above the ligament. I have now observed in two more recent cases that this neuroma makes a visible and palpable swelling, pinching of which produces paræsthesiæ in the three-and-a-half-finger distribution.

" The idea that the compression was produced in the carpal tunnel was entirely due to Dr. Russell Brain, who asked me to explore the cases we described. The nerves disclosed at operation were quite abnormal and resembled in no way the appearance of the median nerve at the wrist in the living subject, the recently dead, or the pickled specimens with which Professor Harris deals. As he has expressed himself so freely in a clinical matter I feel free to say that here he is anatomically in the wrong. True, most of the anatomy books of the last 140 years say that the median nerve *in the palm* is flattened, swollen, and pinkish; but the swelling in our cases resembles Professor Harris in that it goes far too far, extending for at least three inches above the ganglionic enlargement described in the textbooks. As Professor Harris seems so interested in clinical matters and advises on treatment it would perhaps repay him to see one of these operations and verify the pathological appearances described in the article.

" The mockery which followed the discovery of the pathology of the herniated disk has now died away leaving Mixter and Barr holding the field with a great discovery and benefaction to their credit. Now Dr. Russell Brain has just as neatly extricated still another nerve attrition with just as clean-cut a syndrome from the numerous forms of palsied, painful, and anæsthetic hands. I think many will have cause to be grateful for this help in the diagnostic and therapeutic field, in spite of Professor Harris's effort to throw the condition back on to the dust-heap of toxic neuritis.

" One final observation. The patients, now increased to 11 in number, were all relieved by dividing the anterior carpal ligament, although they received no treatment for gonorrhœa. leucorrhœa, pyorrhœa, or old age."—ED. L.

ENOUGH TO EAT?

SIR,—Mr. Strachey's statement (quoted in your leader of March 8) that the poorest third of the nation is eating far more than before the war is nonsense. Of the whole population in 1937 some 10% received rather less than present rations and 5% considerably less. This 15%, or many of them, are eating more: but this is not in any way due to rationing but to the abolition of unemployment. The *Sunday Times* on March 9 published the following table comparing the weekly consumption of the working class in 1937 (including a proportion of unemployed) with present rations:

	Average consumption 1937–38 (*a*)	*Present ration*
Meat	1/6 (*b*)	1/–
Bacon, ham	6 oz.	3 oz.
Bread, flour	$4\frac{3}{4}$ lb. (*c*)	3 lb.
Milk	3 pints (*d*)	3 pints
Butter	$7\frac{1}{2}$ oz.	3 oz.
Margarine	3 oz.	3 oz.
Lard	2 oz.	1 oz.
Cheese	3 oz.	2 oz.
Sugar	$1\frac{1}{2}$ lb.	8 oz.
Eggs	$3\frac{1}{2}$	1

(*a*) Ministry of Labour survey.
(*b*) at present prices.
(*c*) Plus cakes.
(*d*) Plus cream 2d.

Note how much less is the *maximum* present ration than the working-class *average* of 1937—meat and bread two-thirds, fats half, sugar and eggs a third. Hard necessity has considerably reduced the standard of living in this country: not merely the wealthy but the majority of the working classes have substantially less to eat than before the war and have to expend enormously more time to get it, although school meals and works canteens do something to close the gap for those who can use them. Not only are our rations near the necessary minimum but they are monotonous, allowing little scope for individual taste or preference. It is time that claptrap about our being as a nation better fed now than formerly ceased: we are *worse* fed and everybody knows it except apparently the Minister of Food.

Bristol. E. WATSON-WILLIAMS.

DOCTORS' SALARIES

SIR,—Let us all—but let hospital committees in particular—take belated note of Mr. Harold Dodd's strictures upon the scandalously inadequate salaries currently offered to medical men for responsible posts. Although the pound sterling is now no more than half its pre-war value, salaries for registrar appointments requiring higher qualifications remain in the region of £300–400 at best, and other posts are scaled comparably.

Tragically enough, the distinguished members of our profession who are either directly or morally responsible for these rates find plenty of takers in a glutted labour market where the alternative is to emigrate or starve.

Mr. Dodd understates his case, and his specimen budget is pared to the bone. Where is it possible in London for a young doctor to find a flat for less than £5 a week? Or buy food for himself and his wife for much less than another £5?

After five years of war service, and ten years from qualification, I find myself, highly qualified, working twice as long, and probably twice as hard, as any trade-unionist, and daily responsible for life-and-death decisions, for the wages of an incompetent bricklayer. This may have been all very well in an era where my subsequent earnings could possibly have brought some recompense; at least I would have had a sane motive for putting up with it. Today no such thing is true, and a careful study of your advertisements leads me to believe that I may look forward at best to a salary of about £1500 (i.e., £800, 1939) less income-tax. That is the scale the leaders of the profession are not only proffering to their successors, but tacitly (and for all I know, overtly) recommending to the bureaucrats.

I regret bitterly that I was ever so misguided as to enter a profession which rewards both skill and devotion so ill; and if ever I can afford to have a son I will see to it that he is apprenticed to a grocer, and a colonial one at that.

CHIEF ASSISTANT.

THE NATIONAL SITUATION

SIR,—The significance of your correspondent's article last week on Exports and Agriculture is immense. I desire to congratulate THE LANCET most warmly upon its initiative in drawing the attention of a wide circle of professional opinion to this aspect of our affairs. An adequate food-supply is fundamental to all health, and the fact that our food-supply may have to rest for its essentials largely upon our own efforts, within our own shores, is so novel that it will have to be thought over again and again before we can adjust our conceptions to the new conditions of our times.

Food in surplus quantities exists in North America, in Australia and New Zealand, and to a certain extent in South America, but scarcely anywhere else in the whole world. If this food is evenly spread throughout the world's population, the people of this country will find themselves on shorter commons than they have known for many a long day. If we are to have a preferential share of it, we shall have to obtain this by an export effort of absolutely unprecedented extent, directed largely into areas of high industrial productivity which have little room to receive it. Furthermore, we need many other materials, such as metal ores, which are indispensable if our industrial activity is to be maintained. Towards this end our scanty exchange resources will continually need to be realigned.

We need, for example, tungsten, and we need oats. But we can grow oats and we cannot grow tungsten. In such circumstances, the phrase "uneconomic" as applied to cereal production in this country may well be no longer applicable.

All this is taking on a very immediate importance as the dollar loans begin to run out and the floods and the snow force the importance of our own production so painfully to the fore. The fact is that already our own consumption of foodstuffs in this country has fallen as compared with last year. Nor are the levels from which it has declined as high as we had been given to believe. In a recent answer to a question in the House of Commons, Dr. Edith Summerskill stated that the often-quoted figure of 2900 calories per head as a daily British intake was only obtained by dividing the total food moving into civilian consumption by the total number of the civilian population. There is reason to believe that the actual intake, as measured by dietary surveys was, even before the recent decline, no more than 2500 calories per head. The minimum for overall average health and activity is usually taken as about 2400 calories. If these figures are correct, we have reached, and indeed dipped below, the danger-line.

The lesson of all this is terribly clear. It is that a concentration of attention and energy upon home food-production is literally vital, and that a sense of urgency, so far almost completely lacking, must now be the order of the day in tackling this task.

House of Commons. WALTER ELLIOT.

SIR,—Since when has your distinguished journal made itself responsible for propounding political and economic topics thereby inevitably sliding along the nasty path of Party Politics? I cannot—at all events easily—accept the excuse you put forward by stating the truism that medicine is a part of our whole social framework.

Mundesley, Norfolk. S. VERE PEARSON.

⁂ Tuberculosis, to which Dr. Vere Pearson has devoted his professional life, sufficiently illustrates how economics can dispose of what medicine proposes. He will agree that doctors are not purely technicians and should hear more than is audible through a stethoscope. The article in question is a sober analysis of the national situation, written without party bias and leading to conclusions on food-supply, food prices, and urbanisation which (if correct) are important to social medicine.

—ED. L.

Mr. J. F. Foster, formerly registrar of the University of Melbourne and secretary of the Australian Vice-Chancellors' Committee, has been appointed secretary of the Universities Bureau of the British Empire.

Public Health

Testing of Milk

MILK testing is not an end in itself. When any new official test is introduced we have to consider not only its objects and method but also the action to be taken on the results. In announcing (circular 17/1947) a new method—or rather the modification of an older one—for testing non-designated milk, the Department of Health for Scotland makes the object and method clear but is less definite about subsequent action.

The object is strictly limited to the discovery of supplies of milk of poor keeping quality (pathogenic contamination is not dealt with), and the method is a variation of the Hiscox modification of the methylene-blue test. To pass the test, milk, to which has been added, within one hour of the arrival of the sample in the laboratory, a small quantity of methylene blue, must *not* decolorise this dyestuff by 12 NOON on the day after the sample has been taken, the milk and dyestuff being held, meanwhile, at atmospheric shade temperature.

There is little doubt that this procedure gives a much better idea of the keeping quality of the milk—and perhaps also a rather better idea of the cleanliness of production and handling—than the methylene-blue test at 37° as used at present for designated (accredited or tuberculin-tested) milk in England and Wales. It has the same advantages over the resazurin tests now used for both designated and non-designated milk in the National Milk Testing and Advisory (N.M.T. & A.) scheme. Perhaps it is no objection to the new procedure to say that unlike the 10-minute resazurin test of the N.M.T. & A. scheme it cannot in any way be employed as a rejection test—i.e., a test by which a consignment of milk of really poor quality can be spotted *quickly* and prevented from contaminating, and very possibly spoiling, a larger bulk at a collecting depot. The new test will undoubtedly serve as a sound basis for advisory work to the producer, which is its purpose under the new Scottish scheme; but certainly there are advantages in having one which serves both purposes—i.e., as a platform rejection test and as a basis for advising the ignorant, or warning the careless, producer. The 10-minute resazurin test, or a 15-minute methylene-blue test at 37°, meets both requirements fairly well.

If, however, experience in England with the N.M.T. & A. scheme is applicable to Scotland, it may well be found that the factor limiting the usefulness of the test will not be the testing and laboratory end, but the paucity of competent staff available, particularly during the summer months, for speedily giving advice to the farmer whose milk is below standard. It is to be hoped that, with the lower average summer temperature in the northern half of Britain, the difficulties arising from the sheer weight of advisory work in the early days of this scheme will be less acute than those, fortunately now overcome, that impeded the N.M.T. & A. scheme in England in its first two or three years. But if the Scottish scheme is to be successful from the beginning, it may be necessary for the Department of Health, in consultation with the Department of Agriculture, to pay a good deal of attention in the immediate future to the training of those who, with tact and knowledge, are to advise the dairy farmer on hygienic methods of milk-production.

Infectious Disease in England and Wales

WEEK ENDED MARCH 8

Notifications.—Smallpox, 7; scarlet fever, 1217; whooping-cough, 2461; diphtheria, 182; paratyphoid, 4; typhoid, 4; measles (excluding rubella), 12,137; pneumonia (primary or influenzal), 958; cerebrospinal fever, 86; poliomyelitis, 10; polioencephalitis, 0; encephalitis lethargica, 0; dysentery, 69; puerperal pyrexia, 128; ophthalmia neonatorum, 81. No case of cholera, plague, or typhus was notified during the week.

The 7 cases of smallpox were notified at Grimsby.

Deaths.—In 126 great towns there were no deaths from enteric fever, 1 (0) from scarlet fever, 1 (1) from diphtheria, 37 (6) from measles, 15 (1) from whooping-cough, 89 (9) from diarrhœa and enteritis under two years, and 92 (17) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 290 (corresponding to a rate of 29 per thousand total births), including 33 in London.

Parliament

FROM THE PRESS GALLERY

New Grants to the Universities

IN the House of Commons on March 10, in reply to Sir ERNEST GRAHAM-LITTLE, Mr. H. DALTON, Chancellor of the Exchequer, in the course of a statement on new grants to universities, said he had received and considered a report from the University Grants Committee on the financial needs of the universities for the five years 1947–52. The universities would need Exchequer grants on an increasing scale for some time to come, both to effect improvements and to increase the number of students. Parliament would therefore be asked to provide recurrent grants rising from £9 million for the academic year 1947–48 to £9,970,000 for 1948–49 and thence by annual increments of £650,000 to £11,920,000 for 1951–52. The recurrent grants for the present academic year would amount to between £6 million and £7 million. These figures excluded the grants of £500,000 now made to teaching hospitals, which would continue during the financial year 1947–48 and the amount of which for future years had not yet been determined.

The University Grants Committee estimated that the universities' programmes of development would necessitate during the quinquennium non-recurrent grants amounting to £50 million, of which £40 million would be for new buildings and new equipment. Mr. Dalton accepted this estimate and would do his best to meet it. He was advised, however, by the Minister of Works that, even after allowing for a high degree of priority, the best forecast at present possible did not justify the expectation that universities would be able to undertake more than £20 million worth of new building during the quinquennium. He appreciated that this must retard to some extent the expansion of the universities which the Government earnestly desired to see, but for the present it would only be prudent to plan on this restricted basis. The position, however, would be reviewed from year to year. The sum which Parliament would be asked to vote for the financial year 1947–48 was £11,875,000, which included the grants to the teaching hospitals.

Extra Rations for the Sick

On the motion for the adjournment on March 10, Colonel M. STODDART-SCOTT raised the question of the refusal of the Ministry of Food to grant extra rations which had been recommended by doctors. Since rationing was introduced, he pointed out, there had been no drop in the mortality-rate, and there had been an increase in the number of sufferers from gastric ulcers and other gastric complaints, and in nervous and cardiovascular diseases. The rise in the incidence of tuberculosis had also coincided with the reduced diet; and the Minister of Fuel and Power had stated that increased absenteeism in the pits was connected with minor unnotifiable diseases. The survey by the Oxford University Institute of Statistics[1] showed that the present rations for adults were insufficient for their proper maintenance. Sir John Boyd Orr, speaking last August in Copenhagen, said:

> In the United Kingdom it is estimated that the additional food needed to bring the diet of the whole population up to the desired health standard would represent an increase of 25% of meat, and 65% to 75% of other animal products, and fruit and vegetables.

Since then there had been a cut in our bacon ration and the meat ration had been lowered by twopennyworth per week. Therefore, Colonel Stoddart-Scott contended, extra rations were more essential in sickness.

During the last six months of last year 235 cases were refused extra rations by the Ministry of Food. The Special Diets Advisory Committee was composed of ten distinguished physicians and research people. Six of them were consultants, and none was a general practitioner. All had the benefit of age on their side, as the average age was well over 55. This committee, which met only twice during the last six months, drew up a list of diseases with the appropriate diets, but did not deal with the individual cases which were referred to individual members of the committee. That system might have been all right in war-time but it was unnecessary now when the nation was probably worse fed than it was in the war years. Even if the 235 cases had been granted extra rations, it could not have affected the efficiency of our national scheme of rationing. He suggested that if in the administration regions medical advisory committees appointed by the Ministry could be set up, one of whose members would visit border-line cases and make a decision on the spot before a plea was finally turned down, much of the present public anxiety would disappear. Extra rations, he urged, should now be granted not just for the treatment of cases but for the alleviation of discomfort and to help to prolong life.

---

[1] See *Lancet*, March 15, p. 338.

Mr. SOMERVILLE HASTINGS thought that both the public and the medical profession were satisfied with the arrangements, which seemed to have worked admirably for many years. The position of the doctor in private practice was not easy. If he turned down an application for extra milk he might offend his patient. There was a shortage of certain foods, he admitted, and many patients—the majority perhaps—would benefit by extra food and extra milk. But the doctor was strengthened by being able to point out to his patient that his case did not come within the confidential list of diseases eligible for extra nourishment. Some doctors undoubtedly succumbed to pressure from the patient. How else could one explain the extraordinary figures recently obtained from the Ministry, showing that the proportion of people receiving extra milk was more than three times as great in Hampstead as in Tyneside or South Wales? As to the suggested panel of doctors in each area, Mr. Hastings feared that doctors, unwilling to refuse their patients, would call in specialists in a great number of cases.

Dr. EDITH SUMMERSKILL, parliamentary secretary to the Ministry of Food, declared that Colonel Stoddart-Scott's contention that the incidence of disease had been greater during the last few years was not borne out by the public-health statistics. In granting extra food for invalids it was necessary to distinguish between the medical foods needed for therapeutic reasons and medical comforts. The members of the Special Diets Advisory Committee were men who were highly responsible and authorities in their particular field, with a wealth of clinical experience. The committee did not pass judgment on treatment; it advised the Minister on applications from medical practitioners for additional foodstuffs. It was, in fact, an appeal board, and on the whole she thought it had performed its functions well. It was true that the Ministry relied on one or two members of the committee, but these men were highly qualified, and it would be difficult, and certainly not expeditious, to refer each case to every member. The Minister was considering the proposal to set up committees in various parts of the country, but the chief reason why the proposal was opposed at the moment was that medical comforts were to have a bigger place in the Ministry's allocation scheme than heretofore, and she was therefore reluctant to set up committees of busy people who might never be called on to do any work. Some scheme might be devised whereby another doctor could see the patient, and then report to the committee, but she was afraid that this proposal might in effect prove cumbersome, and that it might impose on an already efficient machine another which might never be called upon to function.

QUESTION TIME

Health Surveys

Mr. JOHN MORRISON asked the Minister of Health how many persons were employed by his department to make house-to-house inquiries about health conditions: what was the total annual cost of this activity; and what were the qualifications of those engaged.—Mr. JOHN EDWARDS replied: I assume that the hon. member refers to the monthly survey of illness carried out on behalf of my department by the Social Survey of the Central Office of Information. Each month inquiries are made of a sample of the population by 70 part-time investigators, who are members of the trained staff of the survey. The work is directed by one research officer who is a qualified statistician. The approximate annual cost, including salaries, of this regular inquiry is £12,000.

The *Times* (March 13) announces that the Conservative and Liberal Associations of Luton have approached Dr. Charles Hill, secretary of the British Medical Association, to be their *prospective Parliamentary candidate*. The two associations have joined "to form a common front against Socialism."

Obituary

BRYAN AUSTIN McSWINEY

M.B., SC.D. DUBL., F.R.S.

IN the ten years that Dr. McSwiney spent at St. Thomas's Hospital as professor of physiology and later as dean he became identified to an extraordinary degree with his school of adoption, and his death on March 8 at the age of 52 will be a heavy loss to it.

Born in Chicago, he spent most of his childhood in America, till in 1907 he was sent home to Ireland to finish his schooling at Clongowes Wood College. After a year spent in private study in Germany he entered the University of Dublin in 1912. The outbreak of war interrupted his studies, but in the intervals of serving as a surgeon lieutenant R.N.V.R. (at Gallipoli and elsewhere), as an assistant to the scientific adviser to the Ministry of Food, and as a lieutenant in the R.A.M.C., he took his B.A. in 1916 and his M.B. in 1917. On demobilisation he was appointed assistant to the professor of institutes of medicine at Trinity College, and in 1919 he became lecturer in experimental physiology at the University of Leeds. A year later he moved to Manchester to take up a similar post there, and from 1923 he was also tutor and secretary to the faculty of medicine.

In 1926 McSwiney was nominated for St. Bartholomew's, but in the same week he received a call to Leeds which he accepted on the grounds that there was an honours school and that money had been secured for expansion. "His programme," writes J.K.J., "was a double one—to create an adequate department for a more than doubled entry compared with pre-war days, and to push the honours course as a means of creating a body of interpreters between the clinicians and the pure scientists, who had become rather unintelligible to each other. He had an acute eye for merit, and a gift of encouragement, and he gave an example of ignoring the clock. In result in his short tenure four of his staff passed out to chairs, and several more were dispatched to better themselves. In addition to the number of B.SC. honours students who are now physicians and surgeons, he gave facilities to several B.A. and B.SC. graduates employed on his staff to qualify in medicine in order to work with better coöperation with the practising profession. When he had brough his department to a remarkable level of efficiency and productivity, and had done what he had set himself to do, it became evident that his joy was in the doing, not in the prospect of a calmer life in the house he had built. London seemed to offer more chances of collateral adventures and new experiences." In 1936 he moved to St. Thomas's Hospital medical school.

It was not long before his influence began to make itself felt at St. Thomas's. The physiological curriculum was steadily modernised, and where possible the human subject was made to take the place of laboratory animals in the students' practical work; contacts between physiology and physical medicine were strengthened, and with an increase in staff and equipment an active programme of research was put in hand. In these early years McSwiney's energies were thus largely concentrated upon his own department, but during this time he gained the confidence of his colleagues, and with the coming of war his unique gifts and tireless energy brought him quickly to the fore in the medical school's affairs.

When the bombing in 1940 temporarily reduced the number of beds at St. Thomas's to less than 100 it became essential that the medical school should leave London. This decision was reached in September and McSwiney was asked to act as dean. So well and so energetically did he fill this position that the school reassembled three weeks later in temporary but adequate accommodation at Hydestile and Godalming. During the difficult war years the maintenance of the school and of its standard of efficiency were largely due to his inspiration and energy, and in 1945 his unobtrusive drive ensured uninterruption in working and smoothness of return.

During the whole of this period the school of physiology had been in no way neglected, and he took an active part in initiating and carrying out research himself and in stimulating younger men to like activity. And his scientific status had been steadily growing. In 1944 he delivered the Oliver-Sharpey lectures to the Royal College of Physicians on afferent fibres of the abdominal viscera, and in 1945 the Purser lecture at Trinity College, Dublin, on visceral sensation. In recognition of his work on the physiology of plain muscle and the circulation the Royal Society elected him to their fellowship in 1944. From 1935 to 1945 he served the Physiological Society as treasurer, and at the time of his death he was one of the editors of the *Journal of Physiology*. His enthusiasm for the application of physiology to clinical medicine was the mainspring of his work on oxygen masks and his interest in physical education. He served on M.R.C. committees on the physiology of muscular work and physical exercise, and on traumatic shock. Shortly before the war he made a tour of Europe studying physical education in the different countries, and in his report of this visit to the physical-medicine section of the Royal Society of Medicine in 1938 he urged that the medical man must be trained so as to be able to direct the physical education and nutrition of the school-child.

But from the time he became dean, though not relinquishing his interest in physiology, he devoted his energies to the advancement of medical education as a whole, and he was lately elected to the senate of London University. In August, 1945, he went to Trinidad to examine and to advise on medical education there. After this preliminary survey he went again in April of last year, this time to Jamaica as well as Trinidad. In July he carried out a similar mission to British East Africa, and in December he left for Cairo, India, and Australia. He flew back to this country from Australia in February, arriving in the midst of the cold spell, and contracted bronchitis and bronchopneumonia. He died suddenly when apparently well on the way to recovery.

"Bryan McSwiney's scientific attainments were well recognised when he joined us," writes J. St.C. E., "but it was the stress of the war and the difficulties of the post-war years that brought into the open his real greatness. He was a born administrator and a man of true vision. His mind was set upon the future and he had a conception of medical education which could only have been held by a sensitive person with a wide knowledge of humanity. Yet his dreams were always controlled by an acute sense of what was possible and by a capacity for intense concentration upon detail. He had remarkable gifts of foresight and great business acumen which his friendly personality made it possible for him to employ where others might well have failed. His keen sense of humour and capacity for making contact with people of widely differing backgrounds enabled him to bring to the service of the school a body of knowledge and interest which could only have been gathered by a man of outstanding character.

"Yet with all his urge for improvement and progress, there was a part of his character which was deeply rooted in the past. He loved old furniture and good wine, good conversation and good manners, and he was a discriminating judge of water-colours and etchings. Slovenliness of body or mind he abhorred, and his standards of conduct were based upon a strong but unobtrusive sense of religion and a family life of singular happiness and fullness."

Another colleague continues: "A companionable man, McSwiney disliked being alone, and perhaps above all things he liked talking and listening to talk. For this reason he seemed to resent going to bed: if he could get anyone to stay up with him, he preferred to go on talking into the early hours of the morning rather than to ensure a long night after a strenuous day. . . . The Sherrington School of Physiology has lost a stimulating and inspiring chief, the medical school has lost a dean of drive and vision, the almoners of the hospital have lost a forceful counsellor, and everyone who knew McSwiney has lost a friend."

Dr. McSwiney married Miss Mabel Marie Law and they had three sons and two daughters.

LOUIS COBBETT

M.D. CAMB., F.R.C.S.

Dr. Louis Cobbett, who died on March 10 at the age of 85, was the last survivor of the group of pathologists who carried out the researches for the Royal Commission on Tuberculosis, which ended its work shortly before the outbreak of the first world war.

Born at Weybridge, the third son of Arthur Cobbett, he was educated at Lancing College and Trinity College, Cambridge. He took the Conjoint qualification from St. Thomas's Hospital in 1890, and his F.R.C.S. the following year, and graduated M.B. in 1892. After holding a house-appointment under Sir William MacCormac, he was appointed demonstrator to C. S. Roy, Cambridge's first professor of pathology. In 1894 he was awarded the John Lucas Walker studentship, which he held for the next three years. To this period belonged his work on the diphtheria bacillus, and his M.D. thesis of 1899 was on the action of antitoxin. The outbreaks of diphtheria at Cambridge and Colchester at the turn of the century gave him opportunity to apply his theories epidemiologically, and in the first volume of the new *Journal of Hygiene* he described how an outbreak had been checked by the isolation of contacts. With Nuttall and Strangeways he also discussed the cultural characters of the diphtheria bacillus, based on 950 bacterial examinations.

The Royal Commission on Tuberculosis, set up in 1902, had its origin in the meeting of the British Congress of Tuberculosis the previous year, when Koch, with all the weight of his great authority, dropped a bombshell on the medical world by announcing that human tuberculosis differed from bovine and could not be transmitted to cattle. Lord Lister was in the chair, and Cobbett related how Lister quickly seized the point that though Koch had proved his statement he had not shown that the converse necessarily followed—namely, that bovine tuberculosis could not be transmitted to man. Other Government committees and commissions on tuberculosis had merely taken evidence and "contracted out" the experimental work. But the new commission immediately broke fresh ground by setting up its own experimental farm and research station at Stansted, and there Cobbett, as their scientific investigator, began a series of experiments on animals to explore the pathogenic effects of a large number of strains of tubercle bacillus isolated from human sources, of which lymph-glands formed the majority. This work helped to establish the fact that the bovine strain was pathogenic to man, and the results were published in two large closely documented interim reports in 1907. Cobbett also collaborated with Stanley Griffith in a report in 1913, on tuberculin tests, which was one of the last issued.

When the commission finished its labours Cobbett turned to the production of a textbook embodying the findings of the commission and adding much important matter from the vast store of knowledge he had acquired during these years of work. Unfortunately this book, *The Causes of Tuberculosis*, appeared in 1917 when bacteriologists were thinking more about gas-gangrene and tetanus antitoxin than about the tubercle bacillus, and it did not become as widely known as it deserved. It brought the findings of the commission to bear on seed and soil at a time when the new-founded State tuberculosis dispensaries were beginning to tackle their many problems. Written in a scholarly style, it has become one of the classics of tuberculosis literature. Some years later Cobbett made a further contribution to the subject in a paper on racial immunisation in tuberculosis.

After holding the chair of pathology at Sheffield for a year, Cobbett returned to Cambridge in 1907 on his appointment to the university lectureship in bacteriology, and he held this post till 1929. After his retirement he continued his own research work in the department and gave courses of lectures for part II of the natural sciences tripos. S. R. G., to whom we owe much of this memoir, writes: "Helpful to his juniors, wise, kindly, and courteous, he was always accessible to those who sought information and ready to place his knowledge at their disposal. To me one of the pleasures of visits to Cambridge in the twenties was the opportunity to call upon Cobbett in his laboratory, for he always had something to give out of his wide experience."

MRS. BEDFORD FENWICK, editor of the *British Journal of Nursing* and founder of the British Nurses' Association, died on March 13 at the age of 90. She was matron of St. Bartholomew's Hospital from 1881 to 1887.

Appointments

BELL, R. B., M.R.C.S.: temporary M.O., Croydon airport.
JONES, E. O., M.R.C.S.: dermatologist, Royal West Sussex Hospital, Chichester.
MACLAUGHLIN, J. H., M.B. Belf., D.P.H.: asst. M.O.H., Rotherham.
MOORE, E. H., B.SC., M.B. Lpool, D.P.H.: deputy M.O.H., Warrington.
STEVENSON, J. J., M.B. Edin., D.M.R.: asst. radiologist, Royal Cancer Hospital (Free), London.

The Hospital for Sick Children, Great Ormond Street, W.C.1:
BEYNON, D. W., M.B., M.R.C.P.: resident asst. physician.
DEAN, JOHN, M.B., M.R.C.P.: house-physician.
FETTES, EDITH, M.R.C.S.: resident aural registrar.
GRIFFIN, MONA, M.B. Aberd., D.C.H.: asst. resident M.O., Tadworth Court.
MORRISON, ELIZABETH, M.B. Aberd.: resident anæsthetic registrar.

The South Eastern Hospital for Children, Sydenham:
MCKEAN, C. W. F., M.B. Camb.: dermatologist.
ROLES, F. C., B.CHIR. Camb., M.R.C.P.: pathologist.

Kent County Council:
Asst. pathologists:
BOWERS, V. H., B.SC., M.D. Lond.
CLOSE, H. G., M.D. Lond.
GRIFFITHS, L. L., M.B. Dubl., D.P.H.

St. Helier County Hospital, Surrey:
GOODHART, C. E. D. H., M.D. Camb., D.A.: senior anæsthetist.
STEWART, J. D., M.B. Edin., D.P.H.: director of physical medicine.
TRESIDDER, A. G., C.I.E., M.S. Lond., F.R.C.S.: ear, nose, and throat surgeon.

Examining Factory Surgeons:
CLOHESSY, C. J., M.B. N.U.I., D.P.H.: Ramsbottom, Lancs.
CRETNEY, ERIC, M.B. Manc.: Goole, Yorks.
MCGUINNESS, J. A., L.R.C.P.I.: Leigh, Lancs.
NOLAN, J. P., M.B. N.U.I., D.P.H.: St. Blazey, Cornwall.

Colonial Service:
ANDERSON, N. E. W., M.B. St. And., D.P.H., D.T.M. & H.: senior health officer, Nigeria.
BEAN, A. H., M.R.C.S.: specialist, Nigeria.
BILLIG, REBECCA, B.M. Oxfd: lady M.O., Malaya.
CAMERON, D. L., M.B. Edin., D.T.M. & H., D.P.M.: alienist, medical department, Nigeria.
CHEVERTON, R. L., M.R.C.S.: deputy director of medical services, Nigeria.
EVANS, L. W., B.SC. Wales, M.R.C.S.: deputy director of medical services, Malayan Union.
GALT GAMBLE, MARGARET, L.R.C.P.I.: lady M.O., Gold Coast.
GEMMELL, JAMES, L.R.C.P.E.: M.O., Nigeria.
GILLES, E. O., L.R.C.P.E.: senior health officer, Nigeria.
HALL, R. N., M.R.C.S.: specialist, Nigeria
HAY, I. K., M.B. Aberd.: M.O., Nigeria.
HOLNESS, MARGARET, M.B. Lond., D.T.M. & H.: lady M.O., Nigeria.
HOWARD, A. C., M.D. Lond.: M.O., Cyprus.
HUNTER, WILLIAM, M.B. Glasg., D.T.M.: senior M.O., Nigeria.
JONES, B. S., M.D. Camb., F.R.C.S. Edin.: specialist, Nigeria.
MCQUADE, H. G., M.B. Camb.: M.O., Nigeria.
MENZIES, G. M. M., M.B. Aberd.: senior M.O., Nigeria.
MOIR, K. T., M.D. Edin., D.T.M., D.T.H.: senior specialist, Nigeria.
MONTGOMERY, T. H. L., M.B. Belf., D.P.H., D.T.M. & H.: senior health officer, Nigeria.
NAUDI, J. P., B.SC., M.D. Malta: deputy director of medical services, Nigeria.
NELSON, WALLACE, M.B. Edin.: deputy director of medical services, Nigeria.
POONOOSAMY, VALAYDON, L.R.C.P.E.: M.O., grade 2, Mauritius.
SHEARER, GAVIN, M.D. Glasg., D.T.M.: senior M.O., Nigeria.
SHELLEY, H. M., F.R.F.P.S., M.R.C.P., D.T.M. & H.: director of medical and health services, Cyprus.
SIMPSON, THOMAS, L.R.C.P.I., D.T.M. & H., D.M.R.E.: specialist, Nigeria.
SORLEY, J. T., M.B. Aberd., D.T.M. & H.: specialist, Nigeria.
SUAREZ, CARLOS, M.R.C.S.: M.O., British Somaliland.
VAUGHAN, G. W., M.B. Glasg.: asst. director of medical services, Nigeria.
WARD, THELMA, M.B.: lady doctor, Malaya.
WEIR, H. C., M.B. Dubl.: senior M.O., Nigeria.
WILLIAMS, F. G., M.B. Birm.: M.O., Nigeria.
WILSON, CARMICHAEL, M.B. Dubl.: deputy director of medical services, Nigeria.

Notes and News

MEDICAL LIBRARIES

Mr. W. R. Le Fanu, the librarian of the Royal College of Surgeons, has done a useful piece of work in compiling, with the help of ASLIB, particulars of the medical libraries in the British Isles.[1] He has spread his net so wide that he might have added the Eugenics Society, which has a library of three thousand volumes. But the Middlesex county hospitals, which already have libraries for the use of their medical staff, are rightly included. Some county councils still do not provide this service but other local authorities are planning to provide libraries for all members of the hospital staff as well as the patients. In a supplementary list Mr. Le Fanu gives the information bureaux in the London area. Outside London the libraries and information bureaux are combined in one list, completed by an index to all the libraries and subjects.

MORE HERBS

Mrs. Quelch goes on and on—*Herbs for Daily Use* (1941), *Herbal Remedies* (1945), and now *Herbs and How to Know Them* (London: Faber, pp. 280, 8*s.* 6*d.*)—and definitely up and up. She is a modern Culpeper, with a winning belief in the virtues of the things that grow in meadow and woodland, almost it would seem purposely for the health and comfort of man. And she ropes in her friends to make little portraits of them, which have some of the charm of John Gerard's woodcuts. It matters not that herbs at the moment are outside the main stream of medical thought and practice—that herbalists would not feel at home in a health service. Better far to stay, with Mrs. Quelch, in the pleasant backwaters with the dragonflies and the lazy sunshine, Chaucer and Shelley and Wordsworth benignly looking on. Where we should all be the better for joining them *si opus sit.*

Mrs. C. F. Leyel, who is chairman of the Society of Herbalists, has now completed the second volume of her series of Herbals. This is entitled *Compassionate Herbs* (Faber, pp. 224, 12*s.* 6*d.*) and is limited to herbs used for healing injuries and wounds. Though these have borne the test of centuries of experience they are, she says, entirely neglected in modern surgery—albeit they include cinchona, balsam of Peru, and sphagnum moss. The book has a remarkable index giving the names of the herbs in 10 languages with a high degree of accuracy. There are also 15 attractive line drawings.

REGISTRY OF BONE TUMOURS

A REGISTRY of primary malignant tumours of bones has been set up, with its headquarters at the department of pathology of the Royal College of Surgeons of England, to collect records of cases of primary tumour of bone, including joints and cartilages, especially those in which cure or prolonged alleviation has been attained by treatment. All cases claimed as five year cures will be considered by the committee, but in future only cases in which histological proof of the nature of the tumour, by biopsy or following amputation, can be obtained will be considered. Where histological diagnosis is in doubt, the consultant panel in morbid histology, set up by the Pathological Society of Great Britain and Ireland in conjunction with the British Empire Cancer Campaign and the National Radium Commission, will be consulted. Those interested are invited to send records, with amputation or biopsy specimens, to Prof. R. A. Willis, at the college, Lincoln's Inn Fields, London, W.C.2. Donors will be sent reports on the pathological investigation of specimens received, and in return will be asked for follow-up information regarding patients.

A NURSING BROCHURE

MANY matrons, when they get inquiries from prospective nurses, are obliged to send out dull and out-of-date prospectuses giving no clear picture of the opportunities which training offers, and indeed often repelling candidates by their official tone. Walthamstow Infectious Diseases Hospital has taken the trouble to publish an encouraging illustrated brochure, pointing out that a two-year course leads to qualification as a fever nurse, and that students will be working a 48-hour week, in agreeable country surroundings within a bus ride of London. Their hours of duty are fairly set out: 7 A.M. to 8 P.M., with four hours' break for meals and leisure on four days a week, one whole day off with breakfast in bed, and two free evenings (beginning presumably at 5 P.M.). They get a month's leave yearly. The pictures do not give a false impression of luxury, and it is clear that some trouble has been taken to present a just, as well as a pleasant, picture of what the nurse may expect.

---

[1] *Journal of Documentation*, 1946, 2, 120; in booklet form from ASLIB, 52, Bloomsbury Street, London, W.C.1. 5*s*.

RED BOOKS

FOR the first time since the war the Postmaster-General has been able to issue new editions of his lists of Post Offices in the United Kingdom (1*s.* 6*d.*) and of London Post Offices and Streets (9*d.*). With the current Post Office Guide, also issued at the end of last year, these scarlet paper-covered volumes set out all that the Post Office is ready to do for us. They may also be used as an informal and inexpensive gazetteer, where the spelling and location of the smallest villages can be found.

HELP FOR EUROPEAN LIBRARIES

THE Central Medical Library Bureau set up by the Royal Society of Medicine to fill the gaps in the medical libraries of our Allies has now been at work for a year, and with the aid of a generous grant from the Rockefeller Foundation it has made good progress. Back numbers of many journals are unobtainable and cannot be reprinted, and with the consent of the publishers the bureau's first task has been to supply microfilms of these missing issues. Although production of the film is slower than could be wished, 5000 pages have been filmed in a day. A camera has been discovered which is specially designed for making microfilm, and it is hoped to have four in operation before the end of the second year of the scheme. A suitable microfilm reader has also been selected and many of these instruments have been sent to the beneficiary libraries. The bureau is in touch with libraries in Belgium, Czechoslovakia, Denmark, Holland, Iceland, Norway, Poland, the U.S.S.R., and Greece.

University of Oxford

Dr. A. G. M. Weddell has been appointed reader in human anatomy.

Dr. Weddell, who is 39 years of age, took his M.B. Lond. at St. Bartholomew's Hospital in 1933, and after holding a house-appointment there was awarded a Commonwealth Fund fellowship in 1935. The next two years he spent in America working at Rochester, New York, with Dr. G. W. Corner, and then at St. Louis University with Dr. Ernest Sachs. On his return to this country he was appointed demonstrator in anatomy at University College, London. His early publications include papers on arterial vascular patterns, pathways transmitting sensation of taste, and cutaneous innervation in relation to cutaneous sensibility. During part of his service with the R.A.M.C. during the war he worked in Oxford at the Military Hospital for Head Injuries, and while there he described in our columns (jointly) the clinical application of electromyography and the costoclavicular compression of the subclavian artery and vein. In 1942 he was elected to a Hunterian professorship of the Royal College of Surgeons, and in the following year he was awarded the John Hunter medal and the triennial prize (1940–42) of the college for his research work on the ultimate distribution of the sensory peripheral nerves. During the latter part of the war Dr. Weddell was disembodied from the R.A.M.C. in order to carry out work for the Royal Naval Personnel Research Committee of the Medical Research Council.

University of Dublin

On March 12 the following degrees were conferred at Trinity College:

M.D.—L. R. S. MacFarlane, J. V. Morris.

M.A.O.—D. V. Latham.

M.B., *B.Ch.*, *B.A.O.*—J. R. A. Burns, M. H. Daniels, Kathleen M. Ellis, O. S. J. Redman, H. G. Scott, Jack Steinberg, Margaret P. Steiner, C. D. Turpin.

University of Birmingham

Mr. Hugh McLaren has been appointed first assistant to the professor of obstetrics and gynæcology. Mr. J. A. H. Waterhouse, PH.D., has also been appointed lecturer in human genetics, and Miss Muriel Johnstone, PH.D., officer in charge of records in the department of human genetics.

Association of Sea and Air Port Health Authorities

The 48th annual meeting of the association will be held at the City Hall, Belfast, from May 13 to 15. The medical speakers will include Dr. Lloyd Hughes, who will read a paper on the Hygiene of Crews' Quarters and Provisions, Dr. Samuel Barron (Sanitary Control of Foreshores of Belfast Lough), Dr. Melville Mackenzie (International Health), and Dr. W. G. Swann (Health Control at an Air Port). Further information may be had from the secretary of the association, Health Department, Civic Centre, Southampton.

Royal College of Surgeons of England

At a meeting of the council, held on March 13, with Sir Alfred Webb-Johnson, the president, in the chair, diplomas of fellowship were granted to the following:

L. E. D. Knights, F. S. Mitchell-Heggs, P. I. Hywel-Davies, M. S. Ambrose, I. F. Rose, P. G. Epps, A. J. Walton, L. L. Whytehead, A. C. Bingold, P. T. Savage, J. D. Cronin, R. L. G. Dawson, G. F. Smart, M. H. M. Ryan, Wallace Black, A. M. Abrahams, Ibrahim Demerdash, E. W. Grahame, R. J. Last, L. P. Le Quesne, A. L. Lomas, J. J. MacHale, A. T. Mansuri, A. J. Marsden, N. E. Stidolph, L. P. Thomas, J. V. Todd, M. F. A. Woodruff.

Diplomas of membership were granted to R. M. Forrester and A. M. McCall. The following diplomas were also granted, jointly with the Royal College of Physicians:

D.Phys.Med.—M. H. L. Desmarais, A. J. Enzer, A. J. Martin, J. R, Preston, Alan Stoddard.

D.O.M.S.—J. R. Acfield, M. H. Adams, R. P. Baird, George Bennett, David Black, O. F. Bowes, Louis Boxer, A. V. Clemmey, J. E. Coates, D. B. H. Dawson, A. L. Dick, G. de L. Fenwick, Malcolm Ferguson, R. G. S. Ferguson, A. B. W. Ferreira, C. F. Garfit, O. M. Haarburger, W. H. C. M. Hamilton, L. B. Hardman, Joan Haythorne, A. C. Higgitt, J. C. Hill, B. L. Hoffman, J. M. L. Howat, H. L. Hughes, H. H. Johnson, Anna M. Joyce, J. A. Langille, M. N. Laybourne, V. T. Lees, G. D. Lehmann, Gerald Leiman, Robert Leishman, J. A. N. Lock, J. D. Lodge, Helen C. Longmore, J. G. Louw, R. J. H. McMahon, N. L. McNeil, Kathleen F. Matthews, R. A. Megally, A. D. Milne, J. E. Moffett, T. G. S. Murray, W. C. G. Murray, C. T. Newnham, Marjorie E. Pollard, C. E. Powell, R. E. Rees, K. W. B. Rostron, H. B. Smith, Vincent Tabone, M. A. Weaver, J. E. Wolff, M. H. Wright.

The following were recognised as resident surgical posts for the final fellowship examinations: R.S.O. at Highgate Hospital, London; R.S.O. at Archway Hospital, London; junior R.S.O. and H.S. for one year at St. Stephen's Hospital, London.

During April and May courses of lectures in surgery, anæsthesia, oto-laryngology, and orthopædics will be held at the college. Further particulars will be found in our advertisement columns of March 15.

British Institute of Radiology

Dr. A. E. Barclay, Prof. J. A. Crowther, SC.D., Prof. Sidney Russ, D.SC., and Prof. J. Heyman, M.D., have been elected honorary members of the institute.

The Roentgen award for 1946 has been made jointly to Brigadier D. B. McGrigor and Lieut.-Colonel Eric Samuel for their series of papers on the radiology of war injuries.

Streptomycin in the United States

The price of streptomycin in the United States, which a year ago was about £5 per gramme, is now about 30*s.* per gramme; government officials, says B.U.P., estimate that it will drop to about 22*s.* 6*d.* in July and will settle at about 17*s.* 6*d.* in 1948. The demand is expected to reach about 1 million grammes a month—a little more than three times the present rate of production.

Pasteur Exhibition

An exhibition will be held at the Science Museum, South Kensington, from April 10 to May 26, which includes a chronological account of the chemical and biological work of Louis Pasteur. Another section deals with the Pasteur Institutes established throughout the world for the preparation of sera and vaccines for the combating of disease epidemics. The exhibition has been arranged and provided, with the help of the cultural relations department of the French Foreign Office, by the Palais de la Découverte in Paris, where it has recently been on show. The Science Museum is open, admission free, from 10 A.M. to 6 P.M. on weekdays, and from 2.30 P.M. to 6 P.M. on Sundays.

Health and Tuberculosis Conference

A Commonwealth and Empire Health and Tuberculosis Conference is to be held at the Central Hall, Westminster, London, S.W.1, from July 8 to 10. The speakers will include Mr. Aneurin Bevan (Minister of Health), Mr. A. Creech Jones (Secretary of State for the Colonies), Mr. Walter Elliot, M.P., Lieut.-General Sir Bennett Hance (India), Dr. Jean Gregoire (deputy minister of health, Quebec), Dr. G. J. Wherrett (Canada), Dr. B. A. Dormer (South Africa), Dr. Esmond R. Long (Philadelphia), and Dr. H. Corwin Hinshaw (Mayo Clinic, U.S.A.). Subjects for discussion are: Tuberculosis in the Commonwealth, Sanatorium Design, Aftercare and Rehabilitation, the Human Factor, the National Health Service Act, Colonial Tuberculosis Services, and Prevention and Treatment of Tuberculosis. Further information may be had from the National Association for the Prevention of Tuberculosis, Tavistock House North, London, W.C.1.

REVISION OF THE ANATOMICAL CURRICULUM AT BIRMINGHAM UNIVERSITY *

S. ZUCKERMAN
C.B., M.D. Birm., D.Sc. Lond., F.R.S.
PROFESSOR OF ANATOMY IN THE UNIVERSITY OF BIRMINGHAM

THE general move to raise the scale of university education in Great Britain has provided a new incentive to the reform of the medical curriculum, and one which reinforces the stimulus furnished by the Interdepartmental Committee on Medical Schools in its well-known "Goodenough Report."

The problem of reform is not new, and its ventilation by the Goodenough Committee merely represents the last of a series of reviews which started in 1925 with Abraham Flexner's comparative study of medical education. The trend of most discussion has been a desire to introduce into medical education both the sense of the social needs which such an education should satisfy and the conceptions and methods of the intellectual and critical, as distinct from the informative, side of a university education; more specifically, the desire to depart from vocational instruction, which is largely didactic and descriptive, to an education that has as its basis a general scientific understanding of the mechanisms underlying the processes of health and disease.

To effect such changes it is clearly necessary to revise the curriculum, for one of the objects would be to introduce new "priorities" that will be more in line with present-day trends in knowledge and needs than the old traditional ones, whose effect is to starve important subjects at the expense of topics which continue to be emphasised merely because they always have been.

Anatomists have long been conscious of the fact that they are often regarded by their colleagues in other departments as being among the worst sinners in this respect. Nevertheless they are custodians of a section of medical education which, however much belittled, no-one seems anxious to jettison. Not surprisingly the subject has in some quarters become imbued with a slight sense of inferiority. The result has been bad for anatomists, whose numbers are added to by fewer and fewer scientific recruits, and bad for the subject, since questions of reform have mostly limited themselves to artificial attempts to vitalise the subject by pruning, and by adding to the medical curriculum such matters as genetics, experimental embryology, and so on.

This is clearly not the way which anatomists need follow in contributing to the reform of the curriculum. No useful purpose is necessarily served by uncluttering the subject of unwanted detail merely to create a vacuum which might be filled, according to the taste of the individual teacher, by borrowings from other subjects, or merely to provide more time for another subject to crowd itself with fresh detail, which from both the intellectual and vocational points of view might be no more relevant to the future and immediate needs of the student than were the anatomical details which he would otherwise have been expected to master.

REINTEGRATION OF ANATOMY WITH PHYSIOLOGY

After carefully considering the part anatomy should play in the student's non-clinical education, and in the belief that half-measures were not likely to solve the fundamental difficulties, we have in Birmingham taken the radical step of completely reintegrating the subject with physiology. The term reintegration is used advisedly, for it is only relatively recently that the two disciplines went their separate ways.

It is worth noting this fact carefully, if we are to understand the significance of the change that has been made, and its underlying reasons. Anatomy today is most commonly regarded as the subject which deals with the structure of the body and with the factors concerned in its development and maintenance. Considered as a scientific discipline its domain has become the field of structural organisation. But a hundred, and even fewer, years ago it was being taught and developed as a single subject with physiology. In 1845 William Bowman, whose achievements graced medical science over a large part of the 19th century, and who received his earlier medical education in Birmingham, provided, in collaboration with Robert Todd, one of the first English textbooks of physiology—and it was called not a textbook of physiology but "The Physiological Anatomy and Physiology of Man." At that time anatomy was the basis of most of our beliefs about the function of the organs and tissues of the body. In the preface to his six-volume "Cyclopædia of Anatomy and Physiology," the first part of which appeared in 1835, Todd wrote that it was due to additions to anatomical knowledge that physiology was becoming transformed from "a series of vague and ill-founded hypotheses . . . to a well-arranged science." And if Bowman's (1842) paper on the relation of the micro-anatomy of the kidney to the function of the organ is a sample of what was in mind here, the student of 1946 may well agree that Todd was not exaggerating. It is also worth noting that, two years after the Physiological Society was founded in 1876, an independent *Journal of Physiology* was launched, in spite of the fact that a *Journal of Anatomy and Physiology* had made its appearance some ten years before. It was not until 1916 that the *Journal of Anatomy and Physiology* divested itself of its physiological qualification and became the *Journal of Anatomy*, which is now the organ of the Anatomical Society.

The separation of anatomy as a discipline distinct from physiology appears, so far as the development of medical science in this country is concerned, to have been accidental. It was primarily due to the influence of Sharpey, the first holder of the chair of general anatomy and physiology at University College, London, and his wise maintenance of the need to develop experimental methods in the investigation of biological processes. To this end he initiated a move to separate from anatomy what he termed "practical physiology," and his example was soon followed in Cambridge. The change was a fruitful one so far as the development of biological knowledge was concerned, but the increasing use by physiologists of the experimental method of gaining knowledge, and its sad neglect by anatomists, most of whom remained servants of the old tradition of direct observation of tissues, rapidly created a wide gulf between physiology and its parent subject.

In recent years, however, some anatomists have also taken up the experimental method. The result has been that anatomy departments in this country have become roughly divided into a group in which experimental work of one kind or another is vigorously pursued, and another in which the established morphological tradition is maintained. Not surprisingly, those anatomists who have taught their subject while at the same time pursuing experimental studies have become widely regarded by their anatomical colleagues and physiologists as pseudo-physiologists. The imputation of something wrong in the situation is unwarranted. As G. W. Corner—now head of the department of embryology of the Carnegie Institution of Washington—once put it, the fear that there will soon be no anatomists at all, if every teacher of anatomy becomes a physiologist, is unreal, for the simple reason that anatomists have always been physiologists. One should not, and in fact cannot, separate questions of structure from questions of function. Anatomical

---

* The substance of a lecture given to preclinical students at the opening of the 1946–47 session of the Birmingham medical school.

Penicillin for Germany

According to a Military Government report, quoted by B.U.P., production of penicillin in the British and U.S. zones of Germany is limited to one factory (at Höchst) which is turning out only 50 mega units a month. Production from a new factory which is to be constructed and operated under Allied supervision will, however, end the zones' dependence for supplies on other countries.

Plan for New York as Medical Centre

A plan to make New York a world centre of medical education by combining the resources of 65 big hospitals in the city has been announced by Dr. George Baehr, president of the New York Academy of Medicine. He is quoted by B.U.P. as advocating a central department within the academy for the better utilisation of postgraduate educational and hospital facilities.

Foreign Awards

The following awards have been made to medical men:

Officer in the Order of Orange Nassau.—Surgeon Lieut.-Commander C. G. ROWORTH, M.D. Lond., R.N.V.R.

King Haakon VII Liberty Cross.—Surgeon Captain J. C. SOUTER, M.B. Aberd., R.N.

King Haakon VII Liberty Medal.—Surgeon Commander J. A. KERR, M.D. Glasg., R.N.V.R., Surgeon Commander WILLIAM FLYNN, M.D. Malta, R.N.

King Haakon VII Freedom Medal.—Air Commodore R. R. MACINTOSH, D.M. Oxfd, R.A.F.V.R.

Royal Free Hospital Old Students Association

The reunion dinner of the association is to be held at the Café Royal on April 30. Tickets may be had from the hon. secretaries, Dr. Barbara Mitchell, 6, Church Street, Epsom, or Miss Jocelyn Moore, F.R.C.S., 4, Devonshire Place, London, W.1.

Royal Sanitary Institute

The institute will hold its health congress at Torquay from June 2 to 6. Sections of the congress will deal with preventive medicine, engineering and architecture, maternal and child health, veterinary hygiene, food and nutrition, housing and town-planning, and tropical hygiene. There will also be conferences of medical officers of health, engineers and surveyors, sanitary inspectors, and health visitors. Presidents of the sections and conferences will include Sir Allen Daley, Sir Andrew Davidson, Prof. H. D. Kay, D.SC., Prof. George Macdonald, Prof. R. E. Lane, and Dr. Dorothy Taylor. Further information may be had from the institute, 90, Buckingham Palace Road, London, S.W.1.

Dr. R. R. Race informs us that Prof. Ludwig Hirszfeld is preparing a second edition of his book *Groupes Sanguins* and would be grateful for reprints of English papers on this subject. The address is Wroclaw, Poland, Zakladu Mikrobiologii, Roberta Kocha St. 4. At present up to 4 lb. in weight can be sent, for which a *3d.* stamp is required for the first ounce and a *1½d.* for each additional ounce. The maximum weight for air-mail is one ounce, for which a *5d.* stamp is required.

Diary of the Week

MARCH 23 TO 29

Monday, 24th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.15 P.M. Prof. R. J. V. Pulvertaft: Air-borne Infection.
5 P.M. Prof. John Kirk: Posterior Abdominal Wall.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. *Odontology.* Dr. A. B. MacGregor: Local Penicillin in the Mouth. Dr. G. T. Hankey: Multiple Cysts of the Mandible ? osteitis fibrosa.

Tuesday, 25th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Professor Pulvertaft: Pathology of Diseases of Lymphatic Tissue.
5 P.M. Professor Kirk: Pelvic Wall.
ROYAL SOCIETY OF MEDICINE
8 P.M. *Medicine.* Dr. Adolf Schott: Painful Disability of the Shoulder in Coronary Disease. Dr. Jean Watkinson, Prof. Alexander Haddow, Dr. Edith Paterson, Dr. Inez Ap Thomas: Leukæmia Treated with Urethane. Dr Neville Oswald: Collapse of the Lower Lobes of the Lungs in Children.
LONDON SCHOOL OF DERMATOLOGY, 5, *Lisle Street*, W.C.2
5 P.M. Dr. G. B. Dowling: Lupus Vulgaris.

Wednesday, 26th

ROYAL SOCIETY OF MEDICINE
5 P.M. *Endocrinology.* Mr. J E. Piercy, Dr. W. R. Trotter: Toxic Goitre.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. M. T. Morgan: Health Inspection of Imported Foodstuffs.
CLARKE HALL FELLOWSHIP
4.30 P.M. (New Hall, Lincoln's Inn, W.C.2.) Dr. J. R. Rees: Mental Health and the Offender.
SOCIETY OF CHEMICAL INDUSTRY
6.30 P.M. (Burlington House, Piccadilly, W.1.) *Nutritional Panel.* Mr. Kenneth Mellanby, D.SC.: Human Water Requirements.

Thursday, 27th

ROYAL SOCIETY OF MEDICINE
8 P.M. *Urology.* Mr. R. A. Mogg: Injuries to the Bladder. Mr. D. S. Poole Wilson: Injuries to the Urethra. Mr. Geoffrey Parker: Battle Casualties Involving the Genito-urinary System.
MEDICO-LEGAL SOCIETY
8.15 P.M. (26, Portland Place, W.1.) Dr. C. E. Newman, Mr. R. H. Graveson, PH.D.: Education and Status of the Medical and Legal Professions.
LONDON SCHOOL OF DERMATOLOGY
5 P.M. Dr. H. W. Barber: Seborrhœic Eruptions.

Friday, 28th

ROYAL SOCIETY OF MEDICINE
2.30 P.M. *Epidemiology and State Medicine.* Dr. J. M. Vine: Malaria Control with D.D.T. on a National Basis in Greece.
5 P.M. *Pædiatrics.* Dr. R. W. Cope, Dr. David Asermann: Anæsthesia in Children.
SOCIETY FOR ENDOCRINOLOGY
12 NOON. (Medical School, Hospitals Centre, Birmingham, 15) Symposium on the Adrenal Cortex.

Saturday, 29th

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES
2.30 P.M. (11, Chandos Street, W.1.) Dr. Hamilton Wilkie: Medical Photography—its Application to Venereal Diseases.

Births, Marriages, and Deaths

BIRTHS

BARKER.—On March 12, at Exmouth, the wife of Wing-Commander C. C. Barker, A.F.C., M.B.—a son.
COSIN.—On March 13, in London, the wife of Dr. C. F. Cosin—a son.
DIXON.—On March 10, at Haxby, York, the wife of Dr. D. G. Dixon—a son.
GRAY.—On March 8, at Edinburgh, the wife of Dr. R. F. Gray—a son.
JAMIESON.—On March 11, in London, the wife of Dr. J. G. Jamieson, O.B.E.—a daughter.
JENNER.—On March 12, at Woking, the wife of Dr. Martin Jenner—a son.
JONAS.—On March 8, at Boxmoor, the wife of Dr. Howard Jonas—a son.
KIEFT.—On March 13, at Woking, the wife of Dr. B. T. Kieft—a daughter.
KING.—On March 8, in London, the wife of Dr. E. J. King—a daughter.
MCCRACKEN.—On March 11, at Newcastle-upon-Tyne, the wife of Dr. J. D. W. McCracken—a son.
REID.—On March 12, at Faversham, the wife of Dr. G. O. S. Reid—a son.
SHEE.—On March 12, the wife of Dr. J. C. Shee—a daughter.
STAREY.—On March 8, at Oxford, the wife of Dr. Christopher Starey—a daughter.
STEVENS.—On March 14, at Redhill, Surrey, the wife of Mr. A. Edgar Stevens, F.R.C.S.E.—a son.
STREET.—On March 10, at Lyndhurst, Hants, the wife of Dr. E. W. Street—a daughter.
TAYLOR.—On March 7, at Tunbridge Wells, the wife of Dr. A. W. Taylor—a son.

MARRIAGES

DEWE—FOX.—On March 8, in London, Douglas Dewe, M.R.C.S., major I.M.S., to June Fox.
MACKENZIE—GRENFELL.—On March 5, at Parkgate, Ian Grant MacKenzie, M.B., to Beryl Bruce Grenfell.

DEATHS

ADAMSON.—On March 13, James Weeden Woodhams Adamson, M.D. Durh., of St. Leonards-on-Sea.
BRADLEY.—On March 9, Alwyn Hewett Bradley, M.B. Lond., of Leicester.
COBBETT.—On March 9, Louis Cobbett, M.D. Camb., F.R.C.S., aged 84.
FENTON.—On March 10, at Beaulieu, Hants, Thomas Gerald Fenton, F.R.C.S.
FLEGG.—On March 13, at Cheltenham, Frederick Arthur Martin Flegg, M.R.C.S.
HAWKINS.—On March 9, at Cheltenham, Herbert Cæsar Hawkins, L.R.C.P.E., J.P., aged 83.
HAY.—On March 12, in London, Kenneth Robert Hay, O.B.E., M.B. Camb.
HILL.—On March 11, Arthur Croft Hill, M.D. Camb., aged 84.
LANGFORD.—On March 10, at Bristol, Frederick Charles Langford, M.B.E., M.D. Durh.
MCSWINEY.—On March 8, at St. Thomas's Hospital, London, Bryan Austin McSwiney, M.B. Dubl., SC.D., F.R.S., aged 52.
MORPHEW.—On March 8, at Cromer, Edward Maudsley Morphew, C.M.G., D.S.O., M.R.C.S., colonel, late R.A.M.C.
NICHOLSON.—On March 13, at Louth, Lincs, John Williams Nicholson, M.R.C.S., lieut.-colonel R.A.M.C. retd., aged 91.
ROCK.—On March 10, Cecil Howard Rock, M.R.C.S., late surgeon commander R.N.
TURNLY.—On March 9, at Heathfield, John Edward Litton Alexander Turnly, M.R.C.S.

current vocational and scientific needs of medical education. Essentially, we are breaking away from unreal subdivisions of interest, due to excessive specialisation, so as to bring our research and teaching activities to bear on topics in their entirety.

It is too soon to say how successful the new scheme will prove in practice. In its operation it must necessarily be regarded as experimental and flexible, and subject to such major and minor revision as experience shows to be useful. The character of our professional examinations, and their standard, will necessarily have to be revised in terms of the changes that have been introduced. Further it must be remembered that artificial barriers between subjects in the medical curriculum are not limited to those that have developed between anatomy and physiology; and in time we hope, for example, to reintegrate into our new scheme non-medical biological teaching—particularly when we come to deal with the recombination of our anatomical and physiological Hons. B.SC. and B.SC. courses.

There is little to fear if in all these changes an anatomical department appears to have relegated a part of its independence to serve the needs of functional studies. Atchley (1946), professor of clinical medicine at Columbia University, has pointed out, in a most illuminating discourse on the orientation of medical education, that it should be "gratefully remembered that anatomy was the science which rescued medicine from witchcraft." Today it seems a minor sacrifice to break down the walls which the subject has built round itself in recent times in order to make a start in organising the undergraduate medical curriculum, not by traditional compartments, but on what Atchley has called "the framework of dynamic units," the dynamic units that are constituted, for example, by the working of the respiratory or cardiovascular apparatus, and the only units which are relevant to the modern clinician. Breaking down its administrative walls in no way impairs the status or individuality of anatomy regarded as the science concerned with the problems of structural organisation. It remains an essential foundation for advances in biological and medical knowledge, and its admixture with functional interests will only add to the promise that lies in its own progress.

MEDICAL SPECIALIST

A. B. RAPER
M.D. Leeds, M.R.C.P.
LATE MAJOR R.A.M.C.,
PATHOLOGIST

This paper is part of a comprehensive dietetic survey carried out on African Army personnel. Almost all the subjects studied were Bantu natives drawn from various parts of East Africa.

Our aim was to determine whether the ascorbic-acid intake of the subjects was adequate for their optimum health. This is not a simple matter. Firstly, if direct measurement of the intake shows it to be below that considered adequate in Europeans, it can be argued that the African requires less. The low incidence of scurvy among the subjects has been quoted to substantiate this view; but the non-appearance of scurvy is not good evidence of adequate ascorbic-acid intake. Chronic ill health may appear long before scurvy develops. Secondly, chronic ill health in these subjects is not necessarily due to a deficient intake of ascorbic acid; it is more likely due to other dietary deficiencies and chronic infections and infestations. Thirdly, even if the ascorbic-acid content of the tissues is measured, it is difficult to determine what levels represent an intake adequate for optimum health.

ASCORBIC-ACID INTAKE

All the subjects studied had been on a standard diet for more than two months, and some for several years. We asked 474 men, detained in hospital for a few days with minor complaints, whether during their service they had had access to any additional foods which might contain ascorbic acid. Only 34 of them had had access to such foods, and even these for short and irregular periods. Additional sources of ascorbic acid can therefore be largely ruled out. The Army diet contains 105 mg. of ascorbic acid per man daily, a figure which compares favourably with the recommendations of most authorities. The sources are mainly oranges and vegetables (Anderson 1943).

The daily orange contains about 49 mg. of ascorbic acid. The supply, however, is seasonal, and the substitutes provided often contained much less. The African does not like oranges much because they are sour, and he eats only part of the fruit. For instance, 20 oranges, which had an average content of 44 mg. of ascorbic acid, a figure very near that stated by Anderson (1943), were given to 20 Africans. After the men had finished eating, the discarded portions were analysed for ascorbic acid. Only about 30% of the ascorbic acid had been consumed (highest figure 42%, lowest 18%). The raw vegetable ration contains 25 mg. of ascorbic acid, but, after cooking, the average amount of ascorbic acid daily reaching the soldier was 3–5 mg. The cooks clean the vegetables carelessly, overboil them, clean their pans with alkalis, and throw away the water in which the vegetables are cooked. Thus the daily intake of ascorbic acid falls far short of the calculated amount, the average intake of these subjects being under 15 mg.

RESPONSE OF ANÆMIA TO ASCORBIC ACID

As chronic ill health and low hæmoglobin levels were common in these Africans, it was thought that the low Hb might be related to a low intake of ascorbic acid. Consequently 16 uncomplicated cases of anæmia were investigated. They were selected because they showed no signs of blood destruction, or of blood regeneration such as would occur after an acute illness or a malarial attack. They were subjected to a complete hæmatological investigation, including marrow puncture. All the cases showed the following features:

Mean corpuscular hæmoglobin concentration	range 27·6–44, mean 35·5
Mean corpuscular volume ..	range 76·6–114, mean 93·3
Colour-index	range 0·87–1·29, mean 1·07

The marrows showed a picture of comparative unresponsiveness to the degree of anæmia.

The subjects were then given for seven to ten days a basal diet which contained almost no vitamins, and little protein, but adequate calories and iron. At the end of the period the hæmatological investigations were repeated, but no change in the picture was found. Next, ascorbic acid 700 mg. daily was added to the diet, and after a further seven days the hæmatological investigations were again repeated. This time 6 cases showed a rise of Hb level of not less than 18% and an increase in number of red cells of not less than a million per c.mm., and 3 cases also showed a reticulocyte response between the seventh and tenth days. Although 9 cases showed a response to ascorbic acid, only 3 of them finally attained a figure of 100% Hb with the sole addition of ascorbic acid to the basal diet.

These results,[1] though derived from a small number of knowledge, in the sense of a knowledge of the form and structure of the organs of the body, is essential for the prosecution of physiological studies and for the practice of medicine. Equally, the full investigation of the form of any tissue necessitates a knowledge of its behaviour. As Corner has written :

---

[1] These results are stated here only in brief, because they will be reported later more fully by Lieut.-Colonel O. K. Gayer, R.A.M.C.

> "At some periods in the hands of certain investigators the study of structure has taken the lead, at other times the study of function. There tends in fact to be a series of alternations in this respect in any given field ; for example, the study of cell structure, for a century entirely morphological, is now entering upon a physico-chemical phase, while the physiology of reproduction is at the moment pursued chiefly with the instruments and material of the microscopist. The structure of an organ or tissue is worked at until a new light is thrown upon its action ; but afterwards the complexities of its action in turn require a more fundamental investigation of structure. The progress of a science is achieved by such alternations or by an essentially similar process, namely, the fusion of two viewpoints in a single mind. All the sciences converge toward a common point, for all are concerned ultimately with the study of unstable equilibria ; and it is when two branches of this study converge that fragments of the great puzzle begin to fit together and knowledge is achieved."

Further, to add to Corner's analysis, we have to recognise today the implicit fact that, since the separation of anatomy from physiology in the latter half of the last century and their progressive administrative divergence, continued specialisation has led to such diffusion of boundaries that problems which might classically be described as anatomical have become the research interest of physiologists, and vice versa.

TEACHING OF ANATOMY IN BIRMINGHAM

Anatomy, which has undoubtedly suffered most from the individual specialisation of physiology, biochemistry, and biophysics, will be restored to a basically healthy state if we depart from unreal subdivisions of interest. What has therefore been done in Birmingham is to reinstate, administratively, the relationship which existed between structural and functional studies before anatomy and physiology diverged from common ground.

To this end anatomy in future will retain a separate character only in the dissecting-room, and to all intents and purposes no course of lectures will be arranged which is either purely anatomical or purely physiological. Instead, each course which the medical student attends will provide, in as useful a sequence as can be devised, the required anatomical and physiological knowledge and the necessary indications of current developments. When, for example, the student starts to study the structure of the brain or the form of the heart, he will simultaneously become acquainted with what is known of their activities. By concentrating attention on the function and behaviour of the various organs and tissues of the body, we hope to eliminate details of topographical anatomy which have no scientific value and find little or no application in the vocational fields of surgery or medicine.

Further consequences will be the avoidance of unnecessary overlap and discordant timing, which occur in the separate treatment of anatomical and physiological studies, and a fusion of two different approaches to one goal—knowledge of what the body is and how it works.

The lecture courses have been arranged, according to the following plan, in an introductory, a systematic, and a final coördinating series. The total number of lectures for the five terms is about 290, which from the student's point of view represents an average of $1^1/_2$ lectures a day, and a significant over-all saving in lecture time.

I—INTRODUCTORY AND GENERAL SERIES

Structure of body, general histology, cellular physiology, and integrative mechanisms	*First term* 70 lectures.
Biochemistry and biophysics	
General embryology	

II—SYSTEMATIC SERIES

Blood	*Second term* 72 lectures.
Circulatory system	
Lymphatic system, including cerebrospinal fluid	
Respiratory system	
Digestive system	
Neurology	*Third term* 42 lectures.
Locomotor system	
Metabolism	
Neurology	*Fourth term* 66 lectures.
Special senses	
Excretory system	
Endocrinology, including reproductive system	

III—COÖRDINATING SERIES

Surface and radiological anatomy	*Fifth term* 41 lectures and lecture demonstrations.
Growth and developmental physiology	
Environmental physiology	
Genetics	

Anatomists and physiologists contribute jointly to each course of lectures, in some of which as many four different lecturers participate according to an agreed *plan of sequence in the development of the subject.* Histology and embryology are introduced in the introductory series of lectures and reappear in their relevant positions in each course of the systematic series.

Considerable importance is attached to the final coördinating series of lectures, which represents not only a measure of bringing together in a useful synthesis some of the separate matters considered in the main systematic series, but also an attempt to direct the student's attention to matters which will, or should, be of immediate importance when he begins his clinical studies. To this end a course of lectures on the structural and physiological aspects of postnatal development has been included in this series, as has also a course on genetics.

EXAMINATIONS

In Birmingham, as in most other British medical schools, five terms are set aside for the study of anatomy, physiology, and biochemistry, and hitherto it has been the custom to spread topographical study in the dissecting-room over all five. The practice has also been that students sit separate professional examinations in anatomy and physiology at the end of the fifth non-clinical term.

Henceforth, work in the dissecting-room will be confined to the first three terms only. The first term is given up to the dissection of the limbs and thorax, and the second and third to the abdomen and head and neck. Under these new arrangements students will take their professional examination in topographical anatomy at the end of the third term. An obligatory and running viva-voce examination system has also been introduced into the dissecting-room to check subsequent performance at this first professional examination.

Apart from lectures, the student's time in the fourth and fifth terms, by when he should have adequately covered topography, will be spent in practical work in physiology and biochemistry, and in lecture-demonstrations on surface and radiological anatomy and neurology. A second professional examination will be held at the end of the fifth term, and, though mainly "functional" in character, this will include aspects of structural anatomy. As far as possible it will not be broken up into separate papers representing the existing administrative departments.

FUTURE DEVELOPMENTS

We are fully conscious of the responsibility of having taken the step of rearranging the preclinical curriculum in line with the more advanced proposals that have emerged from recent discussions of possible reforms. We have done so because we are convinced of the need for and rationality of the change in the interests of educational economy. We propose pruning our respective subjects of unnecessary detail and relating them more to the

TABLE II—SATURATION DATES CALCULATED FROM DATA IN TABLE I

Case	Daily intake of ascorbic acid (mg.)	Day of saturation according to blood level	Day of saturation according to urinary output
1	700	13	12
2	700	8	19
3	700	9	19
4	700	10	13
5	700	13	19
6	700	12	10
7	700	14	17
8	700	12	19
9	700	8	19
10	1400	7	14
11	500	14	3
12	500	18	8
13	500	16	3
14	500	26	6
15	500	23	4
16	350	—	5
17	350	28	5
18	350	24	6
19	350	26	2

30 sec. The number of hæmorrhages were then counted with the naked eye and gave the following results:

No. of hæmorrhages	0	1–5	5–10	10–20	over 20	
No. of cases	284	121	27	31	11	(total 474)

It will be seen that 69 out of the 474 subjects showed more than five hæmorrhages in the area. Fox et al. (1940), working with Bantu natives in South Africa, considered that the capillary hæmorrhages could be counted against the black skin. With this we do not agree, and our modification of the test probably explains the greater incidence of abnormal readings obtained in our series.

Though the evidence is in some ways unsatisfactory, these results, taken with others, tend to confirm our belief that the low intake of ascorbic acid in the diet had affected the metabolism of the subjects.

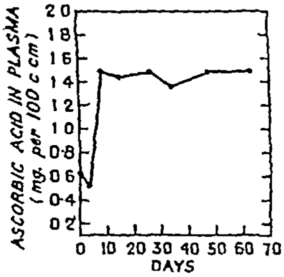

Fig. 1—Ascorbic-acid content of plasma in case 2 when 700 mg. of ascorbic acid daily was added to the diet.

ASCORBIC-ACID CONTENT OF PLASMA

Opinions vary as to whether a single measurement of the ascorbic-acid content of the plasma is an accurate indication of adequate intake. Portnoy and Wilkinson (1938), Ralli et al. (1939), Ralli and Sherry (1941), and others thought that such a measurement was the best criterion of adequate intake, whereas many others hold the opposite view. Prunty and Vass (1943) reviewed the position and concluded that such a measurement was an index of the nutritional state as regards ascorbic acid.

The next question is what figure represents an intake adequate for optimum health. The following figures have been reported by various workers on normal healthy European subjects:

	Ascorbic-acid content of plasma (mg. per 100 c.cm.) Range	Mean
Farmer and Abt (1935)	0·69–2·3	1·24
Taylor et al. (1936)	0·83–2·43	1·61
Greenberg et al. (1936)	0·25–1·48	0·72
Wortis et al. (1938)	0·7 or over	—
Jetter (1938)	1·10 or over	—
Goldsmith and Ellinger (1939)	0·43–1·98	1·11
Croft and Snorf (1939)	0·60–1·12	0·81
Kassan and Roe (1940)	0·13–1·68	0·76
Pijoan and Klemperer (1937)	0·65–2·00	—

It will be seen that the average plasma values in healthy individuals are about 0·9 mg. per 100 c.cm., and that the range of average healthy figures is from 0·13 to 2·43 mg. per 100 c.cm. Approaching the problem from another angle altogether, Prunty and Vass (1943) regarded a figure of 0·4 mg. per 100 c.cm. as the lowest which corresponds to a satisfactory index of ascorbic-acid metabolism.

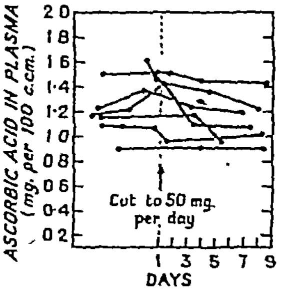

Fig. 2—Ascorbic-acid contents of plasma in 7 subjects who, after saturation with ascorbic acid, were cut down to a maintenance dose of 50 mg. daily.

The technique used in the estimations was that of Farmer and Abt (1935) with two slight modifications: 5 c.cm. of blood filtrate was used instead of 2 c.cm., and a dye solution of which 100 c.cm. was equivalent to 4 mg. of ascorbic acid was used. The results obtained with this technique on a random sample of 19 European officers and N.C.O.'s with an adequate ascorbic-acid intake were as follows:

	Mg. per 100 c.cm.		Mg. per 100 c.cm.		Mg. per 100 c.cm.
Case 1	1·0	Case 7	1·3	Case 14	1·2
,, 2	1·2	,, 8	1·0	,, 15	0·8
,, 3	1·2	,, 9	1·3	,, 16	1·3
,, 4	1·3	,, 10	0·9	,, 17	1·2
,, 5	1·1	,, 11	1·4	,, 18	1·1
,, 6	1·3	,, 12	1·0	,, 19	1·2
		,, 13	1·0		

Range 0·8–1·4 Average 1·1

These figures are higher than those obtained by other workers cited above, probably because of the generous diet.

Estimations of the ascorbic-acid content of the plasma in 361 of the 474 Africans mentioned above gave a mean content of 0·58 mg. per 100 c.cm., with a range of 0·1–0·96 mg. The incidence of different values was as follows:

Content (mg. per 100 c.cm.)	0–0·2	0·2–0·4	0·4–0·6	0·6–0·8	0·8–1·0
No. of cases	2	22	169	134	34

These figures fall well below those of the other workers cited above. It will also be seen that in 24 of the subjects the ascorbic-acid content of the plasma was less than 0·4 mg. per 100 c.cm., which by the most stringent standards would be regarded as indicating an unsatisfactory state of ascorbic-acid metabolism. In 193 of the subjects the level was lower than 0·6 mg. per 100 c.cm. It seems from these figures that about half the subjects had an unsatisfactory ascorbic-acid intake. Bicknell and Prescott (1942) state that plasma values of 0·5–0·7 mg. per 100 c.cm. indicate a state of ascorbic-acid depletion and those of 0·7–1·0 mild deficiency. By these standards all the subjects had at least a mild ascorbic-acid deficiency.

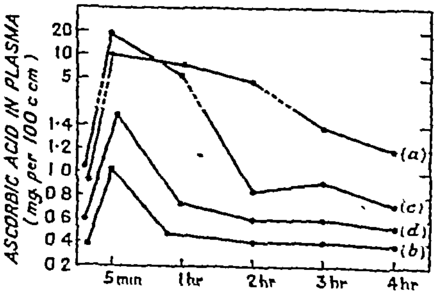

Fig. 3—Ascorbic-acid contents of plasma after administration of 500 mg. of ascorbic acid in (a) normal Europeans; (b) Europeans with ascorbic-acid deficiency (Kastlin et al. 1940); (c) 2 Africans who had had 700 mg. of ascorbic acid by mouth daily for 50 days; (d) 12 Africans on normal Army diet.

The figures are in substantial agreement with those of Fox et al. (1940), but they imply that the lower level cases, suggest that deficient intake of ascorbic acid was a significant feature in the low Hb levels and contributed to the ill health of the subjects.

CAPILLARY-FRAGILITY TEST

Further confirmation of this finding was sought in the capillary-fragility test. This test has been classically used in the detection of ascorbic-acid deficiency states, though the exact relationship between the two is not understood. Its use is recommended by the League Nations Health Organisation (1939). In our opinion test is of doubtful value, because in some cases where have found definite evidence of ascorbic-acid defi- the test has not shown significant correlation. modifications were made in the test owing to the d skins of the subjects. A negative pressure of −300 Hg was applied to the inside of the lip, where there not very much pigment, over an area of 0·5 cm. sq. f

* Cut to 50 mg. a day.

Cases 1–9 were given 700 mg. of ascorbic acid a day; cases 11–15 500 mg.; cases 16–19 350 mg. Case 10 had scurvy and received 1400 mg. a day. The figure shown is the percentage of the test dose passed.

evidence that health was improved. A similar experiment conducted by us produced similar results. There are so many other causes of chronic ill health: deficiency of other food factors, chronic hypoproteinæmia, malarial infestation, and helminthiasis. The multiplicity of these factors should not, in our view, be a justification for omitting to correct each and every one of them in turn.[2]

SUMMARY

The ascorbic-acid intake of 474 Bantu natives in the East African Army was estimated to be under 15 mg. daily.

An attempt was made to correlate this low intake with their state of health by investigating the response of cases of anæmia to ascorbic acid and by measuring capillary fragility. Out of 16 cases of anæmia 9 responded to ascorbic acid, and 14% of the 474 subjects had decreased capillary resistance. It appeared as though ascorbic-acid deficiency was related to their ill health.

The ascorbic-acid content of the plasma was estimated in 361 of the subjects. The mean figure was 0·58 mg. per 100 c.cm., with a range of 0·1–0·96 mg. per 100 c.cm. The figures are well below those regarded as satisfactory in Europeans. The low levels could be raised by the addition of ascorbic acid to the diet. They therefore probably did not represent a physiological low normal level.

Saturation tests were carried out on 19 of the subjects. Intravenous tolerance tests were carried out on 14. It was found that all these subjects were in an unsaturated condition.

Our thanks are due to Brigadier R. P. Cormack, O.B.E., director of medical services, East Africa Command, and Colonel D. Bell, O.B.E., for advice and permission to publish this paper; to the East African Command medical investigation committee for helpful advice and criticism in the preparation of the figures, and in particular to Brigadier E. R. Cullinan, consulting physician, East Africa Command; to Dr. W. Vint and Dr. D. Harvey, of the medical research department, Kenya, for much advice and encouragement; to Staff-Sergeant S. Ibbotson, R.A.M.C., and his staff for help with the techniques of ascorbic-acid determinations, and to Sister E A. McEwan, Q.A.I.M.N.S.(R.), and her staff for a great deal of patient work.

ESTIMATION OF PENICILLIN IN SERUM

USE OF GLUCOSE, PHENOL RED, AND SERUM WATER

SIR ALEXANDER FLEMING
M.B. Lond., F.R.C.P., F.R.C S., F.R S.

CHARLES SMITH
M.B. Lond.

From the Inoculation Department, St. Mary's Hospital, London

MANY methods have been described for the estimation of penicillin in blood-serum. The amount of penicillin present in the blood is often too low for it to be detected by the agar-cup or cylinder-plate methods which are in common use by the manufacturers in the assay of penicillin. The method used must be capable of detecting penicillin in almost undiluted blood-serum, and it is preferable that it should be a micro method so that only small amounts of serum are required and undue bleeding of the patient is avoided.

Such micro methods have been described. Staphylococcus has been used as the test organism and has been grown in slide cells (Fleming 1943) or in modified slide cells (Garrod and Heatley 1944); in these the staphylococcus grows in separate colonies which can be directly observed. In another method staphylococcus has been similarly used, but incubation has been carried out in capillary tubes (Fleming 1943). One drawback to these methods is the difficulty sometimes of being certain whether the staphylococcus has developed or not.

Fleming (1944) introduced a modification by using in slide cells and capillary tubes a hæmolytic streptococcus as the test organism and human blood as the indicator. If the streptococcus grew, hæmolysis took place. This was more satisfactory than the methods in which staphylococcus was used, but occasionally there was trouble in that hæmolysis was not complete even in the control tubes. We therefore sought for another method which would combine simplicity with accuracy, and we describe here a method which seems to have advantages.

INVESTIGATION

Hiss's Serum Water

Media containing pH indicators have been recommended for the titration of penicillin (Fleming 1942). The possibility of using Hiss's serum water was indicated to us by Dr. J. Fielding while he was working in our E.M.S. public-health laboratory. Fielding (1947) has published an article on the use of Hiss's serum water as issued by the London County Council, and a description of a capillary-tube technique which he found in use in this laboratory a year ago.

Hiss's serum water is a culture medium which has long been used for testing the sugar reactions of streptococci and other organisms. It is made by boiling 1 vol. of serum with 3 vols. of distilled water, a fermentable carbohydrate, and Andrade's indicator. When this is done at a pH of 7–8 there is no precipitate and the medium is colourless. When the carbohydrate is fermented by microbic growth the medium becomes bright red and a heavy precipitate forms.

Following Dr. Fielding's suggestion, we tried serum water as issued by the L.C.C. and though it gave promising results it did not seem perfect; so the various constituents of the medium were further investigated.

Optimal Amount of Serum in the Serum Water

Media were made up containing from 50% to 1% of serum in distilled water containing 1% of glucose and an indicator. There was little difference in the results after overnight incubation so long as there was more than 10% of serum present. Naturally the higher the percentage of serum the heavier the precipitate when acid was produced. For convenience we have used as a routine serum water containing 20% of serum.

of the Bantu native is physiological rather than that the ascorbic-acid intake of their subjects was too low. To clarify this point, ascorbic acid was added to the diets of 19 of our subjects for 24–67 days and the ascorbic-acid levels in the blood observed (fig. 1 represents a typical response from one of the cases). At the end of this period the intake was cut down to 50 mg. per day in 7 cases to find out whether the levels attained would be maintained on doses which might be regarded in Europeans as sufficient for maintenance. The results (fig. 2) seem to show that the low plasma levels can be raised to levels regarded as normal in Europeans and can be maintained there. Our view is that the low ascorbic-acid levels found in the plasma represent a deficiency and are not physiological. This view is derived not only from these findings but also from the finding of other evidence of dietary deficiency during this survey (Kekwick and Wright 1946).

SATURATION TEST

The measurement of the state of saturation was introduced to overcome the errors thought to be inherent in the single estimation of the ascorbic-acid level in the plasma. The rationale of the test is based on the assumption that, when a test dose is given, the tissues of the body and the kidneys compete for the available ascorbic acid. When the tissues are satisfied, more and more of the test dose is poured out in the urine. Prunty and Vass (1943) have pointed out that there is a considerable daily variation in the proportion of the test dose poured out in the urine, even when the subject is saturated. They believe that any figure of over 30% of the test dose may indicate a state of saturation.

Table I gives the results obtained with three series of Africans, of whom 9 were given 700 mg., 5 were given 500 mg., and 4 were given 350 mg. of ascorbic acid daily. The table shows considerable fluctuations in the daily output. These fluctuations make it difficult to estimate when the subjects became saturated. On the basis of both urinary output and plasma content table II shows the days on which, in our opinion, the subjects became saturated. As regards the blood levels the day of saturation has been taken as that on which the ascorbic-acid content ceased to rise and the curve became flat (see fig. 1). As regards the urinary output of ascorbic acid, it has been taken as the day on which the patient started to pour out consistently 30% of the test dose. The table exhibits a very curious feature. With the higher dosage the blood figures rose more sharply than with the lower dosage. On the other hand, with the urines the observation is reversed, a larger percentage of the test dose being poured out more quickly with the lower dosage of ascorbic acid per day. At the same time as the patient is pouring out a significant percentage of the test dose, the ascorbic-acid content of his blood is low and still rising. It seems that with lower doses the tissues do not take up ascorbic acid, whereas they do so with the more rapidly rising blood levels.

In 5 of the subjects the amount of ascorbic acid was cut down at the end of fifty days to 50 mg. daily. In only 1 case was the excretion of ascorbic acid greater than intake on two days, an indication that these subjects were not over-saturated.

The conclusions to be drawn from these results are not clear. If the saturated state is desirable for optimal health, the intake of the subjects must be regarded as too low. On the other hand, it may be argued that the saturated state is unnecessary. Most authors consider that a healthy subject should be saturated within two days. None of our subjects fulfilled this condition. The inference is that the ascorbic-acid intake is too low. So far as can be seen from these tests the African behaves towards ascorbic acid in much the same manner as does the European.

INTRAVENOUS TOLERANCE TEST

This test is a modification of the saturation test. The amount of ascorbic acid recommended to be given has varied considerably. We have used the technique of Kastlin et al. (1940), in which 500 mg. of ascorbic acid is given intravenously and the ascorbic-acid content of the blood estimated five minutes, one hour, two hours, three hours, four hours, and five hours later. Theoretically, if the subject is saturated, the ascorbic-acid content of the blood will rise to high levels and fall slowly, as the tissues do not take it up rapidly. If the subject is not saturated the ascorbic acid will be taken up greedily by the tissues and the blood level will not rise so high but will soon fall to the original figure. This test was used because it was found during the survey that many of the subjects had a deficiency small-intestine pattern (Golden 1941). This small-intestine pattern is accompanied by a very low sugar-tolerance curve, and it was thought that the subjects might appear unsaturated because they could not absorb the ascorbic acid given by mouth.

Fig. 3 shows the mean curves obtained from (*a*) normal European subjects, (*b*) deficient European subjects, (*c*) Africans who had 700 mg. of ascorbic acid for fifty days before the test, and (*d*) Africans on the normal Army diet. None of the Africans in groups (*c*) and (*d*) passed 40% of the test dose in the urine within the four-hour period. The Africans given large doses of ascorbic acid for a long period occupy an intermediate position between the well-saturated European and the average African.

These three curves taken together indicate that lack of absorption of ascorbic acid played little part in the saturation tests and that the findings shown in table I represent an unsaturated state. Whether the testing of saturation states in Africans, of whom over 30% have a deficiency pattern of the small intestine and deficient absorption of glucose (Kekwick and Wright 1946), is satisfactory with a test dose given by mouth is not finally settled.

DISCUSSION

The physical state of the African in East Africa is a vital matter in relation to the future of his race. His chronic ill health, a potent factor in his inability to work and to take responsibility, is increased by an extremely low dietetic intake. On joining the Army he was given, in most instances, a far better diet than he had ever had before, but he brought with him his deep-rooted likes and dislikes in regard to food and his habits of cooking, preparing, and eating it. The evidence which we have collected suggests that these habits have contributed to maintaining a low intake of ascorbic acid.

The view that he needs less ascorbic acid because he has always had less is, in our opinion, untenable. During this study we have tried to keep this possibility in mind. The actual intake of these subjects should lead to low levels of ascorbic acid in the plasma. This was indeed found to be so. These low levels can be raised by the addition of ascorbic acid to the diet, which indicates that the levels represent a deficient intake rather than a physiological normal. Saturation tests on the subjects further show that the tissues have a low ascorbic-acid content but can be saturated in much the same way as the tissues of Europeans, both by mouth and intravenously. In short, the ascorbic-acid metabolism of the Bantu native appears to be comparable to that of a European, and therefore his need for ascorbic acid as great.

We do not agree with Fox et al. (1940), who consider that an increase of ascorbic-acid intake in the African's diet is unlikely to improve the African's health. It is understandable that they could show neither startling results from adding ascorbic acid to the diet nor significant evidence that health was improved. A similar experiment conducted by us produced similar results. There are so many other causes of chronic ill health: deficiency of other food factors, chronic hypoproteinæmia, malarial infestation, and helminthiasis. The multiplicity of these factors should not, in our view, be a justification for omitting to correct each and every one of them in turn.[2]

SUMMARY

The ascorbic-acid intake of 474 Bantu natives in the East African Army was estimated to be under 15 mg. daily.

An attempt was made to correlate this low intake with their state of health by investigating the response of cases of anæmia to ascorbic acid and by measuring capillary fragility. Out of 16 cases of anæmia 9 responded to ascorbic acid, and 14% of the 474 subjects had decreased capillary resistance. It appeared as though ascorbic-acid deficiency was related to their ill health.

The ascorbic-acid content of the plasma was estimated in 361 of the subjects. The mean figure was 0·58 mg. per 100 c.cm., with a range of 0·1–0·96 mg. per 100 c.cm. The figures are well below those regarded as satisfactory in Europeans. The low levels could be raised by the addition of ascorbic acid to the diet. They therefore probably did not represent a physiological low normal level.

Saturation tests were carried out on 19 of the subjects. Intravenous tolerance tests were carried out on 14. It was found that all these subjects were in an unsaturated condition.

Our thanks are due to Brigadier R. P. Cormack, O.B.E., director of medical services, East Africa Command, and Colonel D. Bell, C.B.E., for advice and permission to publish this paper; to the East African Command medical investigation committee for helpful advice and criticism in the preparation of the figures, and in particular to Brigadier E. R. Cullinan, consulting physician, East Africa Command; to Dr. W. Vint and Dr. D. Harvey, of the medical research department, Kenya, for much advice and encouragement; to Staff-Sergeant S. Ibbotson, R.A.M.C., and his staff for help with the techniques of ascorbic-acid determinations, and to Sister E. A. McEwan, Q.A.I.M.N.S.(R.), and her staff for a great deal of patient work.

ESTIMATION OF PENICILLIN IN SERUM

USE OF GLUCOSE, PHENOL RED, AND SERUM WATER

SIR ALEXANDER FLEMING
M.B. Lond., F.R.C.P., F.R.C.S., F.R.S.

CHARLES SMITH
M.B. Lond.

From the Inoculation Department, St. Mary's Hospital, London

MANY methods have been described for the estimation of penicillin in blood-serum. The amount of penicillin present in the blood is often too low for it to be detected by the agar-cup or cylinder-plate methods which are in common use by the manufacturers in the assay of penicillin. The method used must be capable of detecting penicillin in almost undiluted blood-serum, and it is preferable that it should be a micro method so that only small amounts of serum are required and undue bleeding of the patient is avoided.

Such micro methods have been described. Staphylococcus has been used as the test organism and has been grown in slide cells (Fleming 1943) or in modified slide cells (Garrod and Heatley 1944); in these the staphylococcus grows in separate colonies which can be directly observed. In another method staphylococcus has been similarly used, but incubation has been carried out in capillary tubes (Fleming 1943). One drawback to these methods is the difficulty sometimes of being certain whether the staphylococcus has developed or not.

Fleming (1944) introduced a modification by using in slide cells and capillary tubes a hæmolytic streptococcus as the test organism and human blood as the indicator. If the streptococcus grew, hæmolysis took place. This was more satisfactory than the methods in which staphylococcus was used, but occasionally there was trouble in that hæmolysis was not complete even in the control tubes. We therefore sought for another method which would combine simplicity with accuracy, and we describe here a method which seems to have advantages.

INVESTIGATION

Hiss's Serum Water

Media containing pH indicators have been recommended for the titration of penicillin (Fleming 1942). The possibility of using Hiss's serum water was indicated to us by Dr. J. Fielding while he was working in our E.M.S. public-health laboratory. Fielding (1947) has published an article on the use of Hiss's serum water as issued by the London County Council, and a description of a capillary-tube technique which he found in use in this laboratory a year ago.

Hiss's serum water is a culture medium which has long been used for testing the sugar reactions of streptococci and other organisms. It is made by boiling 1 vol. of serum with 3 vols. of distilled water, a fermentable carbohydrate, and Andrade's indicator. When this is done at a pH of 7–8 there is no precipitate and the medium is colourless. When the carbohydrate is fermented by microbic growth the medium becomes bright red and a heavy precipitate forms.

Following Dr. Fielding's suggestion, we tried serum water as issued by the L.C.C. and though it gave promising results it did not seem perfect; so the various constituents of the medium were further investigated.

Optimal Amount of Serum in the Serum Water

Media were made up containing from 50% to 1% of serum in distilled water containing 1% of glucose and an indicator. There was little difference in the results after overnight incubation so long as there was more than 10% of serum present. Naturally the higher the percentage of serum the heavier the precipitate when acid was produced. For convenience we have used as a routine serum water containing 20% of serum.

The Indicator

Andrade's indicator, which is present in the L.C.C. serum water, did not seem entirely suitable; so phenol red, cresol red, and brom-thymol blue were tried. Of these, phenol red gave the best results. This indicator gives its maximal colour change between pH 7 and 8. At pH 6·8 it is bright yellow, and at 7·6 cherry red. A very small amount of acid production, therefore, changes the colour from red to yellow. The use of phenol red also enables the pH of the original medium to be observed between 7 and 8, which is the range suitable for growth of the test organisms. The amount of phenol red added is sufficient to give a distinct red colour to the medium in the thin column inside a capillary tube. A good deal more may be added without interfering with the growth of the test organisms.

The Fermentable Carbohydrate

For the most part we have used glucose. This is fermented by a large range of organisms. Various concentrations between 0·5% and 5·0% were tried, and there was not a great deal of difference when streptococcus was the test organism. We decided that 2% was about the optimal strength. Lactose, mannite, and saccharose were also used, but they had no advantage over glucose when streptococcus was the test organism.

The Test Organism

We had previously been using a hæmolytic streptococcus as our test organism, with blood as the indicator (Fleming 1944). We found this same organism eminently suitable in the glucose, phenol red, and serum water mediums. It seemed to produce acid more quickly than did staphylococcus, and the results were rather more clear-cut. The inoculum used was 5 c.mm. of a 24-hour broth-culture to 1 c.cm. of the medium, but there was considerable latitude in this direction.

The Glass Capillaries

Good results were invariably obtained when capillaries made from soda glass were used for incubation. When we used capillaries made from hard glass there was some change in the pH of all the fluids towards the acid side, making the results difficult to read.

COMPOSITION OF THE MEDIUM

As a result of the foregoing work we adopted a medium of the following composition:

Serum	2·00 c.cm.
10% glucose solution	2·00 c.cm.
Distilled water	6·00 c.cm.
Phenol red, saturated solution ..	0·25 c.cm.

For the most part we have used human serum, but horse, sheep, or ox serum can be used. The medium can be made up in bulk, steamed, and distributed in small volumes, or small quantities of 5–10 c.cm. can be made at a moment's notice and boiled for a minute or two over a Bunsen flame. This is an advantage in a hospital laboratory, where small quantities of human serum are always available. For making small quantities it is convenient to keep 10% glucose solution in sealed 1 c.cm. ampoules which have been autoclaved.

TECHNIQUE OF THE TEST

The test is done in the same manner as previously described (Fleming 1944). A suitable amount of the medium is inoculated with the test organism. Serial dilutions of the serum to be tested (25 c.mm. volumes) are made in the inoculated medium on the surface of a paraffined slide. Each of these drops is touched with the end of a capillary tube, and the fluid runs into the tube, which is sealed * and placed horizontally on a 'Plasticine'-covered slide and incubated. By this method the strongest concentration of the test serum is 1 in 2. If it is desired to use almost undiluted serum, 25 c.mm. of undiluted serum can be mixed with 5 c.mm. of 50% serum water containing 5% of glucose and sufficient phenol red and inoculated with five times as many streptococci.

After incubation the tubes in which the streptococci have grown are bright yellow and show a heavy precipitate. There is often an intermediate tube in which there is the colour change but sufficient acid has not been produced to precipitate the serum. The tubes in which growth has been prevented by the penicillin are red or red-violet. The end-point is sharp, and the results are very easily read.

The test can also be done in small test-tubes with the same medium by merely altering the volumes. The results obtained by micro and macro methods are the same.

The results obtained by using a mixture of glucose, phenol red, and serum water as the culture medium and a streptococcus as the test organism have been checked by the methods previously described and have been found to correspond. We have used this method as routine for some months and have found it the most rapid and convenient.

SUMMARY

A rapid, convenient, and accurate micro method of estimating penicillin in blood-serum is described, with a mixture of glucose, phenol red, and serum water as the culture medium and a streptococcus as test organism.

OBSERVATIONS ON FIBRINOLYSIS

EXPERIMENTAL ACTIVITY PRODUCED BY EXERCISE OR ADRENALINE

ROSEMARY BIGGS

RADCLIFFE INFIRMARY, OXFORD

FIBRINOLYTIC activity in the blood of patients with various conditions was described in a previous paper (Macfarlane and Biggs, 1946). Though no definite evidence emerged from these observations that might identify the stimulus leading to activation of plasmin, the proteolytic enzyme of the blood that is almost certainly responsible for lysis of fibrin, it seemed that trauma, fear, or possibly allergy and hypersensitivity were somehow concerned. Since it was considered that further information on the nature of a common activating mechanism underlying these conditions was not likely to be derived at that stage from a continued study of naturally occurring cases, attempts were made to find some method of inducing fibrinolysis in human subjects by experimental means.

At first the production of fear or anxiety was considered as an experimental stimulus. It was soon realised, however, that it is technically difficult in a civilised community to frighten or worry normal individuals at will to the extent that was required. The only readily available material consisted of sufferers from stage-fright in different forms, examination candidates, and those about to engage in various other contests. Some use has been made of them, but opportunities are not frequent, nor are the subjects particularly willing to submit to experiment when in the condition most likely to give good results. Pending the consequently delayed completion of this part of the work, it was decided to explore the possible effects of experimentally produced allergic phenomena, an investigation that led, indirectly, to observations on exercise and adrenaline that are described here.

---

* Sealing is not necessary. The fluid can be run towards the centre of the capillary tube by tilting the tube, and when placed horizontally on the plasticine-covered slide it remains in position. This saves a good deal of time.

METHODS

The methods of collecting citrated plasma and demonstrating fibrinolysis were those used previously (Macfarlane and Biggs 1946). A roughly quantitative estimate of fibrinolysis has been attempted here as follows:

> If all three dilutions of plasma showed lysis within 24 hours, the result was recorded as + + + ; if two lysed, as + + ; and if only one lysed, as +. In any group of observations the "mean fibrinolytic activity" can be obtained by adding up the number of plus signs and dividing by the number of observations. This mean figure can also be expressed as a percentage of 3, the maximum obtainable.

The subjects for these experiments were young adult volunteers, either students or members of the laboratory staff, except where otherwise stated.

EXPERIMENTAL

The discovery of a student who complained of severe urticaria on taking exercise suggested a possible line of investigation of the apparent association between allergic or hypersensitive states and fibrinolysis. In a series of experiments it was found that urticaria could be produced at will in this subject by a certain amount of exercise, and that well-marked fibrinolytic activity developed in his blood, apparently in proportion to the severity of the urticaria.

Further investigation showed, however, that the two phenomena were not related. The urticaria was conditioned by an increase in skin temperature, whereas the fibrinolysis followed exercise independently of temperature. These conclusions were based on experiments in which the effects of exercise or rest in air were compared with those of swimming in cold water or rest in a hot bath, the results being as follows:

Stimulus	*Urticaria*	*Fibrinolysis*
Rest in air	Nil ..	Nil
Exercise in air	++ ..	+++
Exercise in cold water (15 min. at 20° C)	Nil ..	+++
Rest in hot water (15 min. at 43° C) ..	+++ ..	Nil

Attention was therefore directed to the effect of exercise on normal people.

EFFECT OF EXERCISE

Appearance of Fibrinolytic Activity.—A group of 20 normal subjects (16 men, 4 women) took part in a series of experiments that entailed running up and down a spiral stone staircase a stated number of times. The staircase was 39 ft. in vertical height, and the average time for a complete ascent and descent was 50–60 sec. The number of consecutive ascents varied from 2 to 20, the degree of exhaustion of the subject varying not only with the amount of exercise but also with his physical condition. Blood samples were taken before the exercise, immediately after, and after periods of rest. Though blood-pressure, pulse-rate, and mouth temperature were recorded when the blood samples were taken, the results, being variable and apparently not closely related to the other findings, are omitted. The increases in systolic blood-pressure ranged from 15 to 85 mm. Hg.

The results as regards fibrinolytic activity in relation to exercise are given in table I. The control (pre-exercise) observations were all negative except one student in whom a weak positive reaction was obtained, a result that was referred to in the previous paper.* It will be seen that after exercise there is a high incidence of fibrinolysis in the blood samples examined. Of the 33 observations made after three ascents or more, only 2 were negative. A single negative result was obtained among the 29 observations on five or more ascents, the subject concerned being in very good training and little incommoded by his exercise. It will also be seen that there is some proportionality between the amount of exercise and the degree of fibrinolysis recorded.

TABLE I—EFFECT OF EXERCISE ON THE DEVELOPMENT OF FIBRINOLYTIC ACTIVITY IN NORMAL SUBJECTS

No. of ascents	No. of observations	No. with fibrinolysis			
		+++	++	+	0
0–2	28	..	..	1	27
3–4	4	1	..	2	1
5–6	12	9	1	2	..
7–8	5	5	..	..	..
10	10	8	1	..	1
12–20	7	5	..	2	..

In a series of observations on 12 subjects leucocyte and platelet counts were made, besides an estimation of fibrinolysis, before exercise, about half-way through the exercise (8 observations only), and immediately after exercise. The results are given in fig. 1, the values of neutrophils, lymphocytes, and platelets being the means of the percentages of the absolute pre-exercise figures in each subject. There are 4 subjects in each of the exercise groups. Fibrinolytic activity is indicated as a percentage of the maximum that could be recorded in each group. It will be seen from fig. 1 that exercise induces a rise in the absolute number of lymphocytes followed by a later and less definite rise in the neutrophils. The platelets are also increased, but to a lesser extent. Fibrinolytic activity develops early during exercise, showing a significant rise after two or three ascents, or, since these occupy about 1 min. each, after 2 or 3 min. of exercise, and apparently precedes any significant change in the blood picture.

Disappearance of Fibrinolytic Activity.—Three subjects exercised on the staircase for about 7 min., blood samples being taken from each immediately before, immediately after, and at 5-min. intervals during the next 15 min. of rest. Fibrinolytic activity was estimated and leucocyte and platelet counts were made on each blood sample. The results are indicated in fig. 2 by the same method as that used in the previous figure. The results in the 40-min. period, included for completeness, were obtained on 6 subjects who formed part of the group dealt with in fig. 1. It appears from these findings that fibrinolytic activity declines rapidly in the circulating blood after exercise. In no instance was a positive result obtained after 30 min. rest, and even after 10 min. there was a reduction in activity. The blood picture is also restored rapidly towards normal.

Temperature.—To control the possible effect of the increased skin temperature that results from ordinary exercise, observations were made on subjects exercising in cold water. Six volunteers (5 men, 1 woman) swam vigorously for about 15 min. in water at 20° C. At the end of this time all were very cold, and all except the woman, who is an exceptionally strong swimmer, were tired. Blood samples taken before the exercise showed no fibrinolysis, whereas those taken after showed maximal activity in the 5 men and a negative result in the woman. As a control of the effect of cold, 4 volunteers stood for 10 min. in about 4 ft. of water at 20° C. Blood samples taken before and after this procedure were all negative as regards fibrinolysis.

---

* A member of the laboratory staff who, though anxious to take part in the experiment, was nervous and had fainted during the proceedings also gave positive control results and was therefore excluded from the series.

EFFECT OF ADRENALINE

The foregoing results, coupled with the probable effect of fear and anxiety as potentiators of fibrinolytic activity, suggest that adrenaline may be involved in the reaction. Experiments were therefore carried out in which injections of adrenaline were given to normal volunteers and to patients in whom its administration was required for diagnosis or therapy. Also in the experimental group were 3 patients in whom splenectomy had been performed in the past for traumatic rupture of the spleen, and 3 cases of hæmophilia, these being included for reasons mentioned below. In all, 22 experiments were made, 8 of them being on 3 normal volunteers.

TABLE II—EFFECT OF INJECTION OF ADRENALINE ON THE DEVELOPMENT OF FIBRINOLYTIC ACTIVITY IN MAN

Time after injection (min.)	No. of observations	No. with fibrinolysis			
		+++	++	+	0
0	22	..	..	1	21
10	8	6	1	1	..
20	19	14	3	2	..
30	10	3	4	2	1
40	3	..	1	1	1
90 and over	3	..	.	2	1

A solution of 1 in 1000 adrenaline was used in all cases, two preparations being used: adrenaline chloride, prepared by Oxo Ltd., London; and epinephrine hydrochloride, made by Premo Pharmaceutical Laboratories Inc., New York. No significant difference in the results obtained by the different preparations was observed. The solution was given by subcutaneous injection into the upper arm, at the rate of about 0·25 c.cm. per min. The dose varied with the subject, the injection being stopped when symptoms began to appear or when the maximum of 2 c.cm. had been administered. The least amount given was 1 c.cm.

Blood samples were taken for white-cell and platelet counts and estimation of fibrinolytic activity, and the pulse-rate and blood-pressure were recorded in each subject before the injection and at intervals after it had been given. A maximal effect on the blood-pressure was observed 10–15 min. after the start of the injection in most cases, the systolic pressure rising by 20–60 mm. Hg. In all 22 cases the blood samples taken 10–20 min. after the injection showed positive fibrinolysis. The results in relation to time are given in table II, which shows that the effect is more lasting than that of exercise, positive results being obtained up to $1^1/_2$ hours after the injection.

The changes in the neutrophil, lymphocyte, and platelet counts in relation to time after injection are shown in fig. 3. The same method of representation is used as in fig. 1, fibrinolytic activity being recorded as a percentage of the maximum obtainable in each group. The number of subjects in each time group ranged from 4 to 11. Fig. 3 illustrates the rapid and extensive rise in the lymphocyte count after the injection. The neutrophils rise more slowly, and the platelets are less affected than the other elements. As is the case with the results of exercise, the period of maximal fibrinolysis precedes by a short time that of the maximal change in the blood picture.

Three patients who had been splenectomised were included in the series because it was expected that such patients might show a lesser leucocyte and platelet response to adrenaline than normal. All 3 showed maximal fibrinolysis, and a rise in lymphocytes equal to or greater than the average, but the injection produced little change in the neutrophil and platelet counts. Three patients with hæmophilia were included because it has been observed that the effect of chloroform as an activator of fibrinolytic activity in hæmophilic plasma is less than normal (Lewis et al. 1946). The response to adrenaline in the cases observed here, however, was substantially the same as regards both fibrinolysis and the changes in the blood picture as that of the "normal" subjects. The "normal" subjects consisted of the 3 volunteers and 6 male patients in whom malaria was suspected, adrenaline being given to assist the diagnosis; in addition 2 observations were made on a patient receiving adrenaline for angioneurotic œdema. The one positive fibrinolysis result obtained in the 22 pre-injection blood samples was in a man suspected of having malaria, later thought to be suffering from lead-poisoning.

FURTHER OBSERVATIONS

In the previous experiments adrenaline had either been injected or had its natural secretion possibly stimulated by exercise, and both procedures were followed by an increase in the cellular elements of the blood and in fibrinolytic activity. Experiments were therefore carried out to determine if the mere addition of adrenaline or an increased number of platelets or leucocytes to blood or plasma *in vitro* led to fibrinolysis.

Adrenaline.—Adrenaline was added to fibrinogen subsequently clotted by thrombin, and to samples of fresh plasma and of whole blood, these mixtures after short periods of incubation being diluted and clotted as in the usual estimation of fibrinolysis. The adrenaline concentrations used in the blood or plasma ranged from that which might be expected in the blood of the experimental subjects up to a final figure of 1 in 10,000. No fibrinolysis took place in any instance.

Leucocytes.—All formed elements were removed from a fresh sample of "active" (post-exercise) blood by spinning at 20,000 r.p.m. for 30 min. in the cold. The clear supernatant plasma, after dilution and coagulation, showed undiminished fibrinolytic activity. Conversely, the leucocyte and platelet content of a sample of normal citrated blood was artificially raised by adding to it a fresh "buffy-coat" suspension derived from a larger sample of the same blood. Though a general increase of about 300% in formed elements was produced, no fibrinolytic activity could be demonstrated in plasma samples treated in the usual way. The lymphocytosis which occurred in the experimental conditions was also artificially reproduced by adding suspensions of fresh lymphocytes derived from a large volume of blood to a small sample of the same blood. No fibrinolysis was observed to develop.

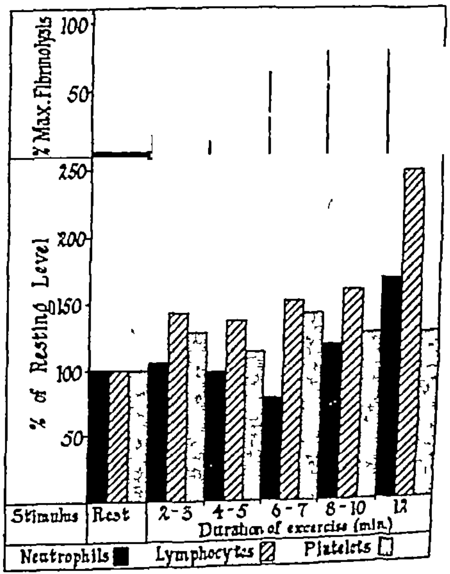

Fig. 1—Effect of various amounts of exercise on development of fibrinolytic activity, and on numbers of leucocytes and platelets, in blood of normal persons.

Adrenaline, Leucocytes, and Platelets Together.—Adrenaline was added to citrated blood with an artificially increased content of leucocytes and platelets, and the mixture incubated. Adrenaline was also incubated with a "buffy-coat" suspension, and with lymphocytes alone, and extracts made of these mixtures were added to citrated blood. In no case was fibrinolysis induced.

DISCUSSION

Strenuous exercise and the injection of adrenaline are stimuli that produce a series of similar effects on the blood of normal persons. Garrey and Bryan (1935) have observed a lymphocytosis that follows short periods of exercise, and Lucia et al. (1937) have recorded a similar change following the administration of adrenaline. A slower rise in neutrophils is also a characteristic result of both stimuli. Our own observations accord with these, and it is now clear that activation of the proteolytic system of the blood is also a common effect. The most reasonable explanation appears to be that the effects observed in exercise are the effects of an increased secretion of adrenaline.

The fibrinolytic activity that has been reported in pathological conditions has usually been associated with states in which increased adrenaline activity might be expected (Macfarlane and Biggs 1946). It therefore seems that adrenaline may be a link in the chain of physiological events that leads to proteolytic activity in the blood of the living subject. That it is probably only a link, however, is shown by the inability of active preparations to induce fibrinolysis in whole blood outside the body. The other parts of the chain must be sought among the vital processes with which adrenaline is concerned in the living organism. Some of its effects, such as the production of a lymphocytosis, neutrophilia, and thrombocytosis, have already been studied. Again, these are changes that do not seem to be directly responsible for fibrinolysis, since the addition or removal of these elements from the blood outside the body has no effect on activity that we have been able to demonstrate.

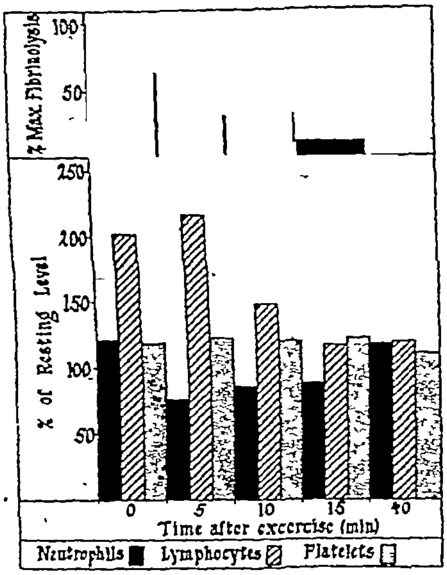

Fig. 2—Changes in fibrinolytic activity, and numbers of leucocytes and platelets, during rest immediately after exercise.

Neither splenectomy nor hæmophilia alters the fibrinolytic response to adrenaline. Ungar (1945) has produced evidence suggesting that the spleen is concerned in the activity of "serum antitrypsin," a substance or factor possibly identical with antiplasmin. Lewis et al. (1946) have found that the development of proteolytic activity after treatment of plasma fractions with chloroform is less than the normal in hæmophilia. We ourselves have some evidence of greater activity of antiplasmin in hæmophilic blood than normal and expected a reduced reaction to adrenaline. The response, however, was normal, and it is clear that further investigation of the abnormalities of hæmophilic plasma is required.

In general, it can be said that fibrinolysis occurs in those conditions in which the subject is exposed to unusual stress. The recognition that there is a definite pattern of response to all such abnormal or excessive stimuli has led to the concept of the "alarm reaction" of Selye (1946). The reaction involves an initial shock phase in which the deleterious effects of the alarming stimulus predominate, and a phase of counter-shock in which these phenomena are reversed. The reaction is accompanied by hypertrophy of the adrenal cortex and involution of lymphoid tissue, and is followed by an increased resistance to a repetition of the same stimulus. Selye included severe exercise, emotional states, and trauma among stimuli producing the alarm reaction, and has observed a rise in non-protein nitrogen during the shock phase. The observation that fibrinolysis occurs almost immediately during exercise or after the injection of adrenaline suggests that it is a feature of the initial phase of the alarm reaction and may be related to the increased nitrogen excretion observed. This and other possible effects of proteolysis occurring as a physiological response to unusual stress must be determined by further experiment.

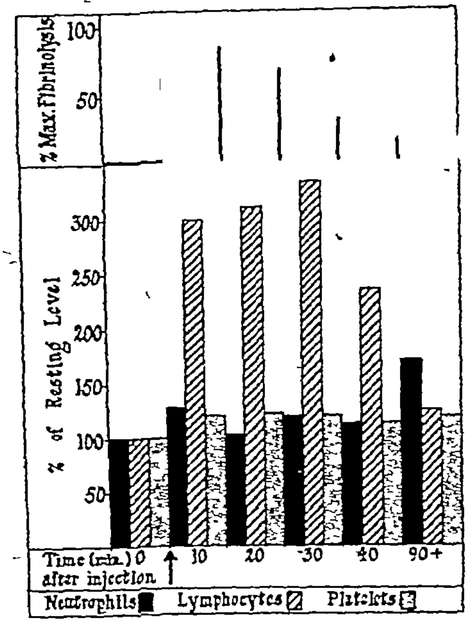

Fig. 3—Effect of injection of adrenaline on development of fibrinolytic activity, and on numbers of leucocytes and platelets, in blood of human subjects.

SUMMARY

Both strenuous exercise and the injection of adrenaline produce fibrinolytic activity in the blood of normal persons.

Both procedures have a similar effect on the blood picture, producing a lymphocytosis, a less marked thrombocytosis, and, later, a neutrophilia.

The addition of adrenaline, leucocytes, and platelets, separately or in combination, to normal blood in vitro does not produce fibrinolysis.

It seems probable that the fibrinolysis associated with exercise, fear, trauma, and some pathological states follows indirectly the stimulation of adrenaline secretion.

Fibrinolysis, indicating the activation of the proteolytic system of the blood, appears to be a component of the initial phase of the alarm reaction of Selye.

We wish to thank the willing and long-suffering volunteers who have submitted to many discomforts during these experiments. We are grateful to Dr. A. J. Shillitoe for help in collecting and examining blood samples. The general investigation of fibrinolysis is financed by the Medical Research Council.

samples taken before and after this procedure were all negative as regards fibrinolysis.

EFFECT OF ADRENALINE

The foregoing results, coupled with the probable effect of fear and anxiety as potentiators of fibrinolytic activity, suggest that adrenaline may be involved in the reaction. Experiments were therefore carried out in which injections of adrenaline were given to normal volunteers and to patients in whom its administration was required for diagnosis or therapy. Also in the experimental group were 3 patients in whom splenectomy had been performed in the past for traumatic rupture of the spleen, and 3 cases of hæmophilia, these being included for reasons mentioned below. In all, 22 experiments were made, 8 of them being on 3 normal volunteers.

TABLE II—EFFECT OF INJECTION OF ADRENALINE ON THE DEVELOPMENT OF FIBRINOLYTIC ACTIVITY IN MAN

Time after injection (min.)	No. of observations	No. with fibrinolysis			
		+++	++	+	0
0	22	..	..	1	21
10	8	6	1	1	..
20	19	14	3	2	..
30	10	3	4	2	1
40	3	..	1	1	1
90 and over	3	..	..	2	1

A solution of 1 in 1000 adrenaline was used in all cases, two preparations being used: adrenaline chloride, prepared by Oxo Ltd., London; and epinephrine hydrochloride, made by Premo Pharmaceutical Laboratories Inc., New York. No significant difference in the results obtained by the different preparations was observed. The solution was given by subcutaneous injection into the upper arm, at the rate of about 0·25 c.cm. per min. The dose varied with the subject, the injection being stopped when symptoms began to appear or when the maximum of 2 c.cm. had been administered. The least amount given was 1 c.cm.

Blood samples were taken for white-cell and platelet counts and estimation of fibrinolytic activity, and the pulse-rate and blood-pressure were recorded in each subject before the injection and at intervals after it had been given. A maximal effect on the blood-pressure was observed 10–15 min. after the start of the injection in most cases, the systolic pressure rising by 20–60 mm. Hg. In all 22 cases the blood samples taken 10–20 min. after the injection showed positive fibrinolysis. The results in relation to time are given in table II, which shows that the effect is more lasting than that of exercise, positive results being obtained up to $1^{1}/_{2}$ hours after the injection.

The changes in the neutrophil, lymphocyte, and platelet counts in relation to time after injection are shown in fig. 3. The same method of representation is used as in fig. 1, fibrinolytic activity being recorded as a percentage of the maximum obtainable in each group. The number of subjects in each time group ranged from 4 to 11. Fig. 3 illustrates the rapid and extensive rise in the lymphocyte count after the injection. The neutrophils rise more slowly, and the platelets are less affected than the other elements. As is the case with the results of exercise, the period of maximal fibrinolysis precedes by a short time that of the maximal change in the blood picture.

Three patients who had been splenectomised were included in the series because it was expected that such patients might show a lesser leucocyte and platelet response to adrenaline than normal. All 3 showed maximal fibrinolysis, and a rise in lymphocytes equal to or greater than the average, but the injection produced little change in the neutrophil and platelet counts. Three patients with hæmophilia were included because it has been observed that the effect of chloroform as an activator of fibrinolytic activity in hæmophilic plasma is less than normal (Lewis et al. 1946). The response to adrenaline in the cases observed here, however, was substantially the same as regards both fibrinolysis and the changes in the blood picture as that of the "normal" subjects. The "normal" subjects consisted of the 3 volunteers and 6 male patients in whom malaria was suspected, adrenaline being given to assist the diagnosis; in addition 2 observations were made on a patient receiving adrenaline for angioneurotic œdema. The one positive fibrinolysis result obtained in the 22 pre-injection blood samples was in a man suspected of having malaria, later thought to be suffering from lead-poisoning.

FURTHER OBSERVATIONS

In the previous experiments adrenaline had either been injected or had its natural secretion possibly stimulated by exercise, and both procedures were followed by an increase in the cellular elements of the blood and in fibrinolytic activity. Experiments were therefore carried out to determine if the mere addition of adrenaline or an *increased number of platelets or leucocytes* to blood or plasma in vitro led to fibrinolysis.

Adrenaline.—Adrenaline was added to fibrinogen subsequently clotted by thrombin, and to samples of fresh plasma and of whole blood, these mixtures after short periods of incubation being diluted and clotted as in the usual estimation of fibrinolysis. The adrenaline concentrations used in the blood or plasma ranged from that which might be expected in the blood of the experimental subjects up to a final figure of 1 in 10,000. No fibrinolysis took place in any instance.

Leucocytes.—All formed elements were removed from a fresh sample of "active" (post-exercise) blood by spinning at 20,000 r.p.m. for 30 min. in the cold. The clear supernatant plasma, after dilution and coagulation, showed undiminished fibrinolytic activity. Conversely, the leucocyte and platelet content of a sample of normal citrated blood was artificially raised by adding to it a fresh "buffy-coat" suspension derived from a larger sample of the same blood. Though a general increase of about 300% in formed elements was produced, no fibrinolytic activity could be demonstrated in plasma samples treated in the usual way. The lymphocytosis which occurred in the experimental conditions was also artificially reproduced by adding suspensions of fresh lymphocytes derived from a large volume of blood to a small sample of the same blood. No fibrinolysis was observed to develop.

Adrenaline, Leucocytes, and Platelets Together.—Adrenaline was added to citrated blood with an artificially increased content of leucocytes and platelets, and the mixture incubated. Adrenaline was also incubated with

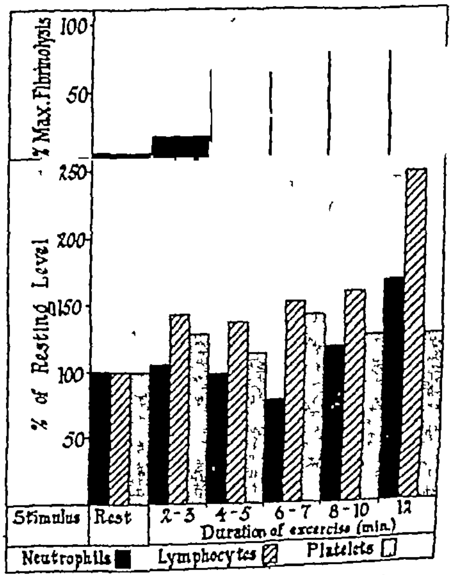

Fig. 1—Effect of various amounts of exercise on development of fibrinolytic activity, and on numbers of leucocytes and platelets, in blood of normal persons.

a "buffy-coat" suspension, and with lymphocytes alone, and extracts made of these mixtures were added to citrated blood. In no case was fibrinolysis induced.

DISCUSSION

Strenuous exercise and the injection of adrenaline are stimuli that produce a series of similar effects on the blood of normal persons. Garrey and Bryan (1935) have observed a lymphocytosis that follows short periods of exercise, and Lucia et al. (1937) have recorded a similar change following the administration of adrenaline. A slower rise in neutrophils is also a characteristic result of both stimuli. Our own observations accord with these, and it is now clear that activation of the proteolytic system of the blood is also a common effect. The most reasonable explanation appears to be that the effects observed in exercise are the effects of an increased secretion of adrenaline.

The fibrinolytic activity that has been reported in pathological conditions has usually been associated with states in which increased adrenaline activity might be expected (Macfarlane and Biggs 1946). It therefore seems that adrenaline may be a link in the chain of physiological events that leads to proteolytic activity in the blood of the living subject. That it is probably only a link, however, is shown by the inability of active preparations to induce fibrinolysis in whole blood outside the body. The other parts of the chain must be sought among the vital processes with which adrenaline is concerned in the living organism. Some of its effects, such as the production of a lymphocytosis, neutrophilia, and thrombocytosis, have already been studied. Again, these are changes that do not seem to be directly responsible for fibrinolysis, since the addition or removal of these elements from the blood outside the body has no effect on activity that we have been able to demonstrate.

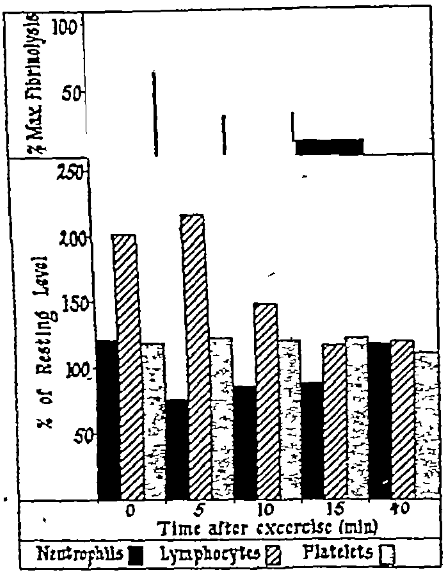

Fig. 2—Changes in fibrinolytic activity, and numbers of leucocytes and platelets, during rest immediately after exercise.

Neither splenectomy nor hæmophilia alters the fibrinolytic response to adrenaline. Ungar (1945) has produced evidence suggesting that the spleen is concerned in the activity of "serum antitrypsin," a substance or factor possibly identical with antiplasmin. Lewis et al. (1946) have found that the development of proteolytic activity after treatment of plasma fractions with chloroform is less than the normal in hæmophilia. We ourselves have some evidence of greater activity of antiplasmin in hæmophilic blood than normal and expected a reduced reaction to adrenaline. The response, however, was normal, and it is clear that further investigation of the abnormalities of hæmophilic plasma is required.

In general, it can be said that fibrinolysis occurs in those conditions in which the subject is exposed to unusual stress. The recognition that there is a definite pattern of response to all such abnormal or excessive stimuli has led to the concept of the "alarm reaction" of Selye (1946). The reaction involves an initial shock phase in which the deleterious effects of the alarming stimulus predominate, and a phase of counter-shock in which these phenomena are reversed. The reaction is accompanied by hypertrophy of the adrenal cortex and involution of lymphoid tissue, and is followed by an increased resistance to a repetition of the same stimulus. Selye included severe exercise, emotional states, and trauma among stimuli producing the alarm reaction, and has observed a rise in non-protein nitrogen during the shock phase. The observation that fibrinolysis occurs almost immediately during exercise or after the injection of adrenaline suggests that it is a feature of the initial phase of the alarm reaction and may be related to the increased nitrogen excretion observed. This and other possible effects of proteolysis occurring as a physiological response to unusual stress must be determined by further experiment.

ANKYLOSING SPONDYLITIS

REVIEW OF 25 CASES

A. M. G. Campbell
D.M. Oxfd, M.R.C.P.
PHYSICIAN, BRISTOL ROYAL AND CITY HOSPITALS; ASSISTANT PHYSICIAN, COSSHAM HOSPITAL

Ankylosing spondylitis may come within the scope of the orthopædic surgeon, the neurologist, or the general physician, and, being on the borderline of so many departments, is important in the differential diagnosis of many other diseases.

The disease is older than man himself, and there is evidence of it in mummified human skeletons and in bears and apes.

Von Bechterew (1893) discussed 5 cases which began with symptoms in the cervical spine and showed paresis of the limbs. Probably these neurological symptoms were really due to some other condition, such as pachymeningitis, since it is known that several of his patients were syphilitic. Strumpell (1897) and Marie (1898) described the better-known form of the disease starting in the lumbar spine. There is no justification for regarding the two types as being in any way distinct except in their site of onset. Since these classic accounts many papers have appeared on the subject, the most exhaustive review being that of Geilinger (1918).

Accounts of the pathology of the disease are very rare owing to the difficulty of obtaining necropsy material, but Freund (1942) has described his findings in a patient who died from another cause. He found connective tissue had spread from both the bone-marrow and the capsule into the joint space and attacked the cartilage by lacunar erosion. This replacement of cartilage might affect one or both articular surfaces. Fibrous or bony union ultimately took place, and the joint space disappeared. Within the joints various stages of inflammation were seen, the connective tissue showing a round-cell infiltration and congested blood-vessels. Cartilage was replaced by fibrous tissue in the intervertebral disks, which ultimately ossified. This ossification was both protective and adapted to the more static function which the spine undertook as the inflammatory phase passed. No true degeneration of cartilage took place. The change from cartilage to fibrous tissue may be reversible, and bone, fibrous tissue, and cartilage may all be present together.

INCIDENCE

Fletcher (1944) considered this disease to be increasing. This has been my impression also, but it is difficult to prove, as the military Services contain a high proportion of the susceptible age-groups. Junghanns (1932) found, in 10,000 necropsies, 8 cases of ankylosing spondylitis. Hare (1940) found 6 cases in 1179 cases of rheumatic disease. In 1000 cases of rheumatic disease seen by me at a spa there were 12 cases, and among 1000 general medical outpatients there were 2 cases. The orthopædic surgeon should see the highest percentage.

The following remarks refer to 25 cases seen by me: 7 in civilians and 18 in the Royal Air Force.

Sex-incidence.—In this series there are 24 male cases to 1 female, and this may be due to the much lower incidence of W.A.A.F. personnel. Buckley (1931) reports an incidence of 10 males to 1 female, and Swaim (1939) 4 males to 1 female. The sex-incidence is therefore predominantly male.

Age-incidence.—The third decade was the commonest age of incidence, but the first symptom is often manifested some years before the disease forces the patient to seek medical advice. The average age-incidence of this series is 22 years. Fletcher (1944) gives an age-incidence of 38·4 years in a civilian series, and this discrepancy is probably explained by the difference between civilian and Service incidence. In this group the 7 civilians show a higher age-incidence by 8 years.

Familial Incidence.—Geilinger (1918) recorded three families in which more than one blood relation had contracted the disease, and Ray (1932) recorded the disease in identical twins. Two of my patients were identical twins who developed the disease in different countries at the same time. Another two were brothers. A fifth patient had a brother who had died from ankylosing spondylitis, and a sixth patient had an uncle and a brother with the disease. Payling Wright told me in 1945 that he knew of a father and son similarly affected. This family history is significant and is inadequately emphasised in the English literature.

There is no evidence of any *occupational incidence.*

REMOTE AND RECENT PRECEDING DISEASES AND HISTORY OF IRITIS

Iritis has long been associated with ankylosing spondylitis and other rheumatic diseases, but it is often overlooked. Teschendorf (1935) recorded 9 cases and suggested that all cases of iritis should have spine and pelvis radiographed. Fritz (1937) claims the association of iritis with spondylitis is found in 20% of cases, and the figure for my series is 24%. Blair (1942) suggested that a deficiency of sulphur might be a factor in this association, and cited as evidence the fact that cartilage and ocular tissues contain a much higher content of chondroitin sulphuric acid than does any other tissue. The present view of iritis is that it is an inflammatory reaction to many non-specific infections. In my series, association was recorded with other diseases in a similar category: purpura, chronic lupus erythematosus, psoriasis, and nephritis. Edström (1940) had noted nephritis in his cases. More striking was the history of asthma and erythema nodosum in 2 of my cases (one of the two pairs of brothers).

Numerous infective conditions were found to precede more directly the spondylitic process—e.g., gonorrhœa, non-specific urethritis, tuberculosis, tonsillitis, and lung abscess. Some patients had a history of a fall, but these were too few to emphasise.

SIGNS AND SYMPTOMS

The onset of ankylosing spondylitis is insidious and in the early stages difficult to diagnose.

Stiffness of the Back.—The first symptom in most cases is stiffness of the back, with lack of mobility. The patient may notice that, where previously he was able to perform certain actions, he now finds increasing difficulty. An example of this was a medical student who noticed that his ability to play tennis was becoming impaired but only reported this symptom after seeing a case of ankylosing spondylitis demonstrated in the wards. Stiffness of the spine seriously interferes with any bending movements and sometimes with rotation and lateral movements of the neck. Cases show lack of mobility and spasm of the muscles of the back.

Joint Pains.—The second most important symptom is pain, which is later than limitation of movement. Usually as a result of involvement of the sacro-iliac joints, pain begins low in the back and is apt to pass down the back of both legs later; the pains may gradually spread up the entire spinal column. Rarely the disease may begin in the cervical spine.

Root Pains.—As the disease begins to involve the vertebræ, root pains begin to develop and are characteristic, radiating from the back round the abdomen and thorax. In the thoracic-region these pains radiate along the intercostal nerves and are made worse by deep breathing and coughing. The patient finds that he has pain, limitation of movement, and a tight feeling in his chest, particularly when waking in the morning. On locomotion the spinal muscles often go into spasm; more rarely there are local tenderness and atrophy.

The head is usually carried forward and the chin depressed. No rheumatic nodules are found. Pains of this type in the lumbar region may be severe and will simulate chronic abdominal conditions, such as biliary and renal disease.

These are the three classic symptoms of ankylosing spondylitis; but, before passing on to the more general symptoms, it is perhaps best to mention the differential diagnosis of these symptoms. Taken together the stiffness and pain may be confused with: (1) conditions of the soft tissues, such as panniculitis and fibrositis, which arise in the lumbar region but are far less limiting of mobility, more easily treated by massage, and less chronic and insidious; (2) strains of the sacro-iliac joint, which usually follow trauma; and (3) sciatic neuritis.

Many cases of ankylosing spondylitis are thought to be suffering from sciatic neuritis because the pains due to the involvement of the sacro-iliac joints have led to the erroneous assumption that the sciatic nerve is involved. The differential diagnosis is made by careful neurological examination. Ankylosing spondylitis reveals no abnormal neurological physical signs, nor does stretching of the sciatic nerve cause pain. Other causes of low-back pain due to pelvic disease should rarely be mistaken for ankylosing spondylitis if an adequate urinary, rectal, and gynæcological examination is made. The root pains characteristic of this disease are accompanied by a great loss of mobility of the thorax, and this alone should be sufficient clue to the diagnosis. The chest expansion may be nil, and other diseases producing radicular pain, such as spinal-cord tumours and tabes dorsalis, can be excluded by neurological examination.

Finally, pain and immobility of the spine may be secondary to disease of the vertebral column, of which by far the most important to exclude are Pott's disease and osteomyelitis of the vertebræ. Pott's disease of the spine can simulate ankylosing spondylitis very closely, and the diagnosis can only be made more certain by early radiography and by finding tuberculous foci elsewhere. Osteomyelitis is usually much more acute and only rarely takes the form of a chronic abscess of the vertebræ. Paget's disease of the spine is diagnosed by radiography, and secondary carcinomatosis of bone should always be considered.

These three symptoms—stiffness, joint pains, and root pains—taken together are important in this disease, but other more general symptoms must be enumerated. Pyrexia and anorexia may be present, and ankylosing spondylitis must be considered in the diagnosis of pyrexia of unknown origin, particularly in tuberculosis, whether general or local, and in infective endocarditis. In neither of these diseases does one usually find the three main symptoms enumerated above. Lastly, other joints, apart from the sacro-iliac and spine, may be involved; the commonest of these are the shoulder and clavicular joints, the right shoulder being more commonly affected than the left.

When other joints become involved, the differential diagnosis from rheumatoid arthritis becomes important. In rheumatoid arthritis the peripheral joints are most involved; this is never so in ankylosing spondylitis. Rheumatic nodules are never found in ankylosing spondylitis but are present in rheumatoid disease. The older textbooks still associate spondylitis with gonorrhœa, an entirely erroneous generalisation, although gonorrhœa may precede the onset of spondylitis in a few cases. Gonococcal arthritis is an acute pyogenic arthritis, with acute inflammation of joints unlike the more chronic involvement in ankylosing spondylitis. Lastly, osteoarthritis of the spine in elderly persons is a degenerative disease which is easily differentiated by radiological evidence of osteophytic outgrowth and lipping of the vertebræ.

LABORATORY AND RADIOLOGICAL AIDS TO DIAGNOSIS

The most important investigation in suspected ankylosing spondylitis is *radiography* of the spine and pelvis. If radiography reveals obliteration of the sacro-iliac joints, or sclerotic change round these joints, an early case of the disease must be considered. As the disease progresses, the spinal ligaments begin to show patchy or complete ossification. Radiological changes in the hips and shoulder-joints arise very much later.

The *blood-sedimentation rate* is much raised during the active phase of the disease, and in one case an average of these readings over six weeks was 105 mm. in an hour (Westergren).

The *blood acid phosphatase* is also raised in certain cases, though in this series it was never more than twice the normal and never reached the high figures recorded in carcinomatosis of bone.

Robinson (1940) found that *tuberculin-sensitivity tests* were 30% higher in ankylosing spondylitis than in rheumatoid arthritis. Perry (1940a) showed that the antistreptolysin titre was normal.

The *blood picture* in this series showed a mild microcytic anæmia. In two cases an eosinophilia of over 5% was found, but one patient had been on service in India.

PROGNOSIS

The prognosis is surprisingly good, so long as longevity is concerned. Most patients die in the fifth decade. Death is usually from intercurrent infection, but the handicaps of immobility and pain make life a burden to the sufferer from ankylosing spondylitis. Much depends on the patient's psychological adaptation to his condition and the limitation it involves. The disease waxes and wanes for no reason and may suddenly flare into activity with over-exertion; realisation of this is most important in treatment.

TREATMENT

The treatment is unsatisfactory. We must, if possible, treat any antecedent disease or infection and clear any sepsis. Treatment of the disease is largely symptomatic. During the acute stages the patient must be completely rested in bed, and sometimes a plaster bed is useful. After the acute phase has subsided, re-education and moderate mobility must be attempted. Probably the most valuable treatment is that of deep X-ray therapy to the spine. This relieves the pain very satisfactorily, local irradiation appearing to be better than a general spread. Gold therapy is disappointing. Protein-shock treatment relieves the symptoms in the acute stages, and autogenous whole blood and intravenous T.A.B. have both been successful in certain cases. In conjunction with Wing-Commander A. G. Cross it was found in one case that whole-blood injections up to 15 c.cm. intramuscularly helped to improve both the iritis and the pain of the ankylosing spondylitis. Penicillin and sulphonamides are of no value. The patient is often underweight and debilitated and should receive a liberal and balanced diet.

These patients should be helped psychologically; the rigidity and peculiar carriage of the head make them very conscious of their disease and, like people with facial burns, they may tend to avoid society. Every effort must be made to make them forget their disability and lead a normal life. Too much sympathy and dependence must be avoided, and limited exercise in the quiescent phase encouraged. It has been suggested that patients who develop spondylitis are of an abnormal mental make-up. It is not fully realised that chronic illness of this type produces psychological reaction in the most stable temperament, and spondylitic patients are no exception. Breathing exercises are most important to counteract the fixation of the thorax. In the quiescent phase many patients continue active work, and one R.A.F. officer, despite limited head movements, flew a Spitfire in the Battle of Britain.

Swimming and cycling are the most suitable exercises, and hydrotherapy is of use in re-education of the limbs.

DISCUSSION

The incidence of this disease in more than one member of a family is emphasised in this series, and this suggests there may be an inherent susceptibility to develop ankylosing spondylitis. The occurrence in identical twins suggests this, and, in the words of Perry (1940b) describing the incidence of acute rheumatism in identical twins, "there may be genetically determined differences in susceptibility but needing an environmental stress or strain for the disease to become manifest." It is considered that in ankylosing spondylitis the position is the same. The environmental stress is not specific, and there is a parallel in the development of thought about the ætiology of polyarteritis nodosa. The ætiology of the latter long remained obscure, and many infections were blamed in turn, such as gonorrhœa, syphilis, and rheumatic fever, but the work of Spiegel (1936) and Rich (1942) has proved that polyarteritis nodosa is due in some cases to an inherent or acquired local tissue hypersensitivity precipitated by widely differing antigens. There is also some parallel to the association between preceding infections and the onset of rheumatic fever and nephritis. An attempt has been made in this paper to link the association of such diseases with cases of ankylosing spondylitis. It is believed that many of these diseases are closely related.

It has been suggested that ankylosing spondylitis bears some relation to the metastasis of carcinoma of the prostate in the similar distribution of the lesions and the rise in the acid phosphatase. The dramatic effect of stilbœstrol on the carcinomatous prostate suggests its trial in spondylitis.

In this series the acid phosphatase was never raised so high as in prostatic cancer, and this agrees with Buckley's (1945) suggestion that the rise is merely an index of osteoblastic activity. A similar rise is found in rickets. It cannot yet be said that no endocrine disturbance is present, but there is no satisfactory evidence of any imbalance. The predominance in males and the onset of the disease after puberty may be of significance. Ssamarin (1928) removed the parathyroids in one case, but without benefit to the patient.

SUMMARY

Twenty-five cases of ankylosing spondylitis are reviewed.

The ætiological factors of inheritance and environmental influences are discussed.

The incidence of other conditions of possible allergic ætiology, especially iritis, is emphasised.

In diagnosis the essential features are spinal stiffness, joint pain, and root pains. The differential diagnosis is discussed.

Methods of treatment are outlined, particularly the psychological management of the case.

It is considered that the most likely cause is an inherent susceptibility precipitated by some environmental stress. The evidence of possible endocrine factors is discussed.

My thanks are due to the D.G.M.S., R.A.F., for permission to publish this paper, and to orthopædic specialists in the R.A.F. for referring cases to me.

STABILISATION OF PENICILLIN SOLUTIONS WITH SODIUM CITRATE

L. HAHN
M.D. Prague
MEDICAL SUPERINTENDENT, U.N.R.R.A. GLYN HUGHES HOSPITAL, BELSEN, B.A.O.R.; LATE MEDICAL REGISTRAR, NUNEATON E.M.S. HOSPITAL

AQUEOUS solutions of penicillin retain their potency at room temperature for a limited period, the stability varying according to the constituents of the different manufactures. Hughes,[1] testing samples supplied by the Therapeutic Research Corporation (T.R.C.), found that the penicillin solution in distilled water remained stable for about seven days. Assays carried out with the same manufacture in our laboratory (T.R.C.330; 4 units per c.cm.) gave the following results: diameter of inhibition rings with the agar-cup method immediately 16 mm.; after twenty-four hours 13 mm.; after forty-eight hours 13 mm.; and after seventy-two hours 13 mm.

Pulvertaft and Yudkin[2] have shown that phosphate has a stabilising effect on the rate of destruction of penicillin by heat, and that the effect is not due to control of pH but to a specific action of the phosphate ion.

I here describe the stabilising effect on sodium penicillin of sodium citrate dissolved in physiological NaCl solution. This property was accidentally discovered when sodium citrate in 0·9% NaCl solution was used as control in experiments with penicillin and citrated blood and produced a remarkable stabilising effect on sodium penicillin. The stabilising effect is not due to any changes of pH. Sodium citrate proved to be less effective than the combination of sodium citrate and sodium chloride.

METHOD

Two batches of sodium penicillin—T.R.C.392 (containing 615 units per mg.) and 330 (units per mg. not specified)—were tested. One tablet containing sodium penicillin "10,000" units was dissolved in sterile distilled water to give a solution of "40" units per c.cm. This was dissolved 1 : 10 in the solution under test, thus providing "4" units per c.cm. For the individual assay 0·1 c.cm.—i.e., sodium penicillin 0·4 unit—was used.

The agar-cup method (Fleming) was applied with petri dishes of 11 and 17 cm. diameter and 27 and 50 c.cm. of nutrient agar respectively. The suspension of a 24-hour standard[3] *Staph. aureus* agar culture, 0·1 c.cm. and 0·2 c.cm. respectively, was spread over the whole surface of the agar plate and, after 15 min. drying in the incubator, holes 9 mm. in diameter were punched. These cups were filled with 0·1 c.cm. of the penicillin solution under test, and the plates then incubated for fifteen hours. After incubation the diameters of the rings of inhibition, minus 9 mm. representing the diameter of the cup, were compared. The solutions to be heated were kept in ampoules.

---

[1] Hughes, K. E. A. Penicillin Therapy and Control in 21 Army Group, 1945, p. 327.

[2] Pulvertaft, R. J. V., Yudkin, J. *Lancet*, 1946, ii, 265.

[3] Characteristics of our *Staph. aureus* strain—(1) liquefaction of gelatin: after 3 days at 17° C; (2) hæmolysis: after 24 hours at 37° C; (3) coagulation of plasma: positive; (4) agar colony: circular, orange, glistening; (5) mannitol: acid.

RESULTS

Destruction of Penicillin at 100° C in Citrate and Phosphate.—4 units of sodium penicillin dissolved in 1 c.cm. of a solution consisting of 1 part of $M/5$ sodium citrate and 4 parts of 0·9% NaCl solution, and 4 units of sodium penicillin dissolved in 1 c.cm. of $M/15$ phosphate were tested (1) immediately; (2) after heating at 100° C for 15 min.; and (3) after an hour's heating at 100° C in the water-bath. The rates of destruction of the penicillin solutions were as follows:

	Diameter of Inhibition Ring (av. of 3 assays) in mm.	
	Citrate-NaCl	*Phosphate*
Immediate..	19	19
After heating for 15 min. ..	18	16
After heating for 1 hr.	16	0

It will be seen that under the conditions used in this assay the stabilising effect of citrate-NaCl is greater than that of phosphate.

Rate of Destruction of Penicillin in Salt and Blood Mixtures at 37° C.—Samples of various penicillin-salt mixtures, each containing 4 units per c.cm., were kept in test-tubes at 37° C in the incubator for various periods. Complete sterility was assured in all experiments as proved by controls. The results for (1) a solution of 1 part of $M/5$ sodium citrate and 4 parts of 0·9% NaCl; (2) 0·9% NaCl; (3) $M/15$ phosphate; and (4) blood 4 parts and sodium citrate 1 part were as follows:

	Diameter of Inhibition Ring (av. of 3 assays) in mm.			
Hours	*Citrate-NaCl*	*NaCl*	*Phosphate*	*Blood+citrate*
0	18	19	18	18
12	18	7	14	10
24	18	6	14	10
48	18	0	12	6
72	18	0	12	5

It will be noted that the loss of potency of the penicillin solutions after three days was 0 for the citrate-NaCl mixture, whereas in saline the bacteriostatic level of the penicillin rapidly declined.

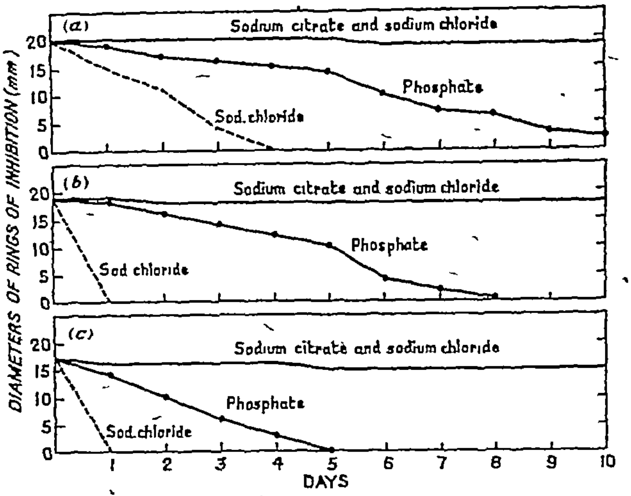
DIAMETERS OF INHIBITION RINGS (MM.) OBTAINED AFTER STORAGE FOR 0–10 DAYS AT ROOM TEMPERATURE

Days	1 unit of penicillin sodium dissolved in 0·9 % NaCl solution with sodium citrate in concentrations of:						
	$M/1$	$M/5$	$M/10$	$M/20$	$M/50$	$M/100$	None
0	15	15	15	15	15	15	15
1	15	15	15	15	15	15	0
2	15	15	15	15	15	15	0
5	13	14	14	14	14	14	0
10	12	13	13	13	13	13	0

Stability of Penicillin-salt Mixtures after Heating at 100° C.—Samples containing 4 units of sodium penicillin T.R.C.330 per c.cm. dissolved in citrate-NaCl and phosphate $M/15$ were filled in ampoules and sterilised at 100° C for 10 min. The effect on the stability, the ampoules then having been kept at room temperature, was as follows:

	Diameter of Inhibition Ring (av. of 3 assays) in mm.	
Days	*Citrate-NaCl*	*Phosphate*
0	20	21
4	20	19
8	19	17
13	18	15
23	18	14

It will be seen that, in accordance with the findings of Pulvertaft and Yudkin,[2] penicillin-phosphate solutions tolerated sterilisation without a considerable loss of potency. In citrate-NaCl solution the loss of activity was very small, even after twenty-three days.



Rates of destruction of penicillin in different concentrations at body temperature: (a) 3 units per c.cm.; (b) 2 units per c.cm.; (c) 1 unit per c.cm.

Assays with Various Penicillin Concentrations.—To ascertain whether changes of penicillin concentration influenced the results, assays were carried out with 1, 2, and 3 units of sodium penicillin per c.cm. of the salt mixtures. T.R.C.330 was used. The mixtures tested were (1) sodium citrate $M/5$ 1 part, 0·9% NaCl solution 4 parts, pH 7·0; (2) 0·9% NaCl solution, pH 6·2; and (3) $M/15$ phosphate, pH 7·0; 1, 2, and 3 units of sodium penicillin were tested separately in each solution. The accompanying figure illustrates the rate of destruction of the penicillin solutions at 37° C.

Effects of Citrate Concentration on Stability of Penicillin.—In an attempt to find the optimal concentration of citrate effecting stabilisation of penicillin, various fractions of molar citrate solutions were tested. The following table gives the results obtained with $M/1$, $M/5$, $M/10$, $M/20$, $M/50$, and $M/100$ citrate solutions combined with 0·9% NaCl solution.

The table shows that there was no correlation between the concentration of the citrate ion and its stabilising effect on sodium penicillin within the limits of this experiment. But further observations using 0·9% NaCl and sodium-citrate concentrations ranging from $M/200$ to $M/1000$ showed that an optimal stabilising effect was produced by concentrations of $M/300$ to $M/400$. After heating at 100° C for 30 minutes, solutions of sodium penicillin containing 5 units per c.cm. were then found to have retained 84% of their potency. The effect of such lower molar concentrations on the stability of penicillin solutions at room temperature is being followed up. It would be tempting to correlate the effect with the Ca or Mg ion; but only one manufacture could be used for the experiments, and the impurities and their amounts are unknown, so any such attempt would be futile.

PRACTICAL APPLICATIONS

It appears that sodium citrate combined with 0·9% NaCl solution has a considerable stabilising effect on sodium-penicillin solutions, and this effect is much greater than that of phosphate as described by Pulvertaft and Yudkin.[2] It is thus possible, by using sodium citrate in saline as solvent, to preserve penicillin solutions at room temperature for long periods. Such solutions can be sterilised by boiling them for 10 min. and kept stable at room temperature in ampoules so prepared.

SUMMARY

A mixture of sodium citrate in concentrations of $M/1$ to $M/100$ and sodium chloride 0·9% in the proportion of 1 : 4 stabilises sodium-penicillin solutions at 100° C and

at room temperature. Preliminary work suggests that, with penicillin-sodium solutions up to 5 units per c.cm., an optimal stabilising effect is produced with sodium-citrate concentrations of *M/300 to M/400.*

The stabilising effect of this saline-citrate mixture exceeds that of phosphate.

I am indebted to Mr. W. Kaufmann, technical assistant to the Glyn Hughes Hospital, for his coöperation and practical help.

GENERALISED SKIN SENSITIVITY

FOLLOWING LOCAL APPLICATION OF ACRIFLAVINE

REPORT OF A CASE

J. Martin Beare
M.D. Belf.
LATE SURGEON-LIEUTENANT R.N.V.R.

Generalised dermatitis following local application of acriflavine is not common; and, since the acridine group of drugs * is among those most commonly used for surface antisepsis, it is of interest to record a case. The subject is of topical interest, too, because within the past year attention has been drawn to local sensitisation to acriflavine. According to MacKenna (1946): "Acriflavine seems no longer to be the innocuous remedy which it was generally supposed to be."

A Royal Naval rating, aged 39, reported on Sept. 14, 1945, with a small superficial ulcer, about the size of a shilling, on the anterior aspect of the lower third of the left leg, which had been knocked a few days previously. He had had no previous skin disease and no previous sulphonamide or flavine therapy. There were no varicose veins present. He was treated twice daily with sulphanilamide powder and gauze soaked in 1/1000 acriflavine in arachis oil over the powder until Oct. 1.

Sept. 24: he had a fleeting, roseolar, and very irritating rash on the trunk and upper parts of the arms and legs. This rash faded within a few hours, but its significance was not appreciated at the time.

Oct. 1: daily application of Castellani's paint was prescribed.

Oct. 8: there being no change in the ulcer, it was decided to try sterile lint under an elastic plaster dressing and leave undisturbed for four days.

Oct. 12: there being still no change in the ulcer patient was put to bed, with the leg raised and splinted, and the ulcer was cleaned with soap and water, and penicillin cream was applied every four hours.

Oct. 21: pus was forming, and dressing was changed to gauze soaked in 1/1000 aqueous solution of acriflavine.

Oct. 26: still no change; dressing changed to sulphathiazole paste.

Oct. 27: signs of acute local sensitisation dermatitis, with vesiculation, redness, and swelling, which was thought to be due to the sulphathiazole paste. Treatment was immediately changed to 1/1000 acriflavine in arachis oil. Next day patient had acute eczematous dermatitis of the whole of the left lower leg. Acriflavine was discontinued, and soft paraffin on sterile gauze was applied.

Nov. 6: suddenly, within a few hours, patient developed a temperature of 102° F, with much constitutional disturbance and a generalised roseolar erythema, affecting the whole body but most marked on the trunk.

Nov. 9: generalised desquamation took place, and the temperature dropped to normal, but a weeping dermatitis remained on both legs and the sides of the head.

Apart from a few relapses, which were less severe than the original eruption, patient gradually improved with various local applications, such as calamine lotion, calamine cream, &c., until Dec. 13, when the skin was normal, except on the left leg, which was still very red below the knee. The ulcer had healed. Throughout the illness the nails and hair remained unaffected.

Nov. 25: skin tests were made with sulphanilamide, sulphapyridine, sulphathiazole, and sulphadiazine powders, each suspended in a small amount of water, sulphathiazole paste, and arachis oil, since it was thought that the condition was probably a sensitisation reaction to a sulphonamide.

Nov. 27: there being still no reaction, the skin tests were repeated, with, additionally, gauze soaked in 1/1000 acriflavine from the stock bottle included among the test substances. Through each of the test drugs a small scratch was made. Next day there was a vesicular eruption where the acriflavine had been applied. This subsided within two days. There were no reactions to any of the other test substances.

Nov. 28: white-cell counts, including differential counts, were within normal limits. There was no suggestion of eosinophilia.

The rating was last seen on Jan 9, 1946, feeling fit, and with no sign of abnormality of the skin.

DISCUSSION

Most of the published work relating to the toxic effects of the acridine drugs refers only to liver damage following intravenous administration in the treatment of gonorrhœa 15–20 years ago (Cullinan 1931, Birch 1931, Heathcote and Urquhart 1930, Davis 1924, Davis and Sharpe 1932, Meleney and Zau 1925). The liver damage was of the same type as that which arises after the parenteral administration of other drugs, such as arsenic and insulin. Other authors have, however, claimed that acriflavine does not commonly cause liver damage when given intravenously (Hanschell 1931, Simpson 1931). The explanation of this difference of opinion probably lies in the now widely accepted theory that infective hepatitis, developing in patients receiving injections of any kind, is due to contamination of the syringe and/or needles, transmission of the organisms responsible for the disease from patient to patient taking place in this way (Bigger 1943, Beattie and Marshall 1944, Salaman et al. 1944, Sheehan 1944, Witts 1945).

Dermatitis of parts of the body exposed to sunlight, after intravenous acriflavine, has been recorded (Assinder 1936, Fessler 1942), but there seem to be few reports of dermatitis following the local application of the acridine drugs—the only example I could find was that of Young and Hawking (1938), who described local acriflavine dermatitis in an Indian patient. These writers said they could find no other reference to such sensitivity, and Browning (1943) remarks that "toxic damage in man from acriflavine or proflavine absorbed from wounds has *not* occurred. Skin *idiosyncrasy* has been met with, though very rarely."

In the present case a fleeting rash appeared after ten days' local acriflavine therapy, and the rash disappeared in a few hours, though treatment was unaltered. At that time the rash was considered irrelevant. When, however, acriflavine was applied for the second time, the local lesion slowly improved, but after seven days signs of sensitivity suddenly appeared on the leg. Then, though the acriflavine dressings were changed to sterile dressings of soft paraffin on gauze, generalised dermatitis developed ten days later.

I wish to thank Dr. I. H. McCaw, Dr. F. F. Kane, and Dr. R. Hall for their interest and help in the preparation of these notes; Miss M. Hislop for her skilled typing; and the Medical Director General of the Royal Navy for permission to publish.

Medical Societies

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION

THE paper-reading session of the association's quarterly meeting was held on Feb. 21, with Prof. D. K. HENDERSON, the president, in the chair.

Psychiatry and the Population Problem

Dr. C. P. BLACKER indicated the importance of adequate records; it was not difficult, he said, to secure accurate demographic data, such as numbers of brothers, sisters, and children, duration of marriage, and consanguinity of parents. This information would provide material for research and could also be used administratively, for example in forecasting probable requirements for institutional beds, allowance being made for the effect of the ageing of the population. He considered that statistical records should not be too rigidly centralised, but should be available in the various regions, where they would stimulate research.

SURVEY OF SUBNORMAL TYPES

Mr. R. CARADOC JONES discussed a survey carried out some years ago in the Merseyside area. The numbers studied were large, and a control sample of normal working-class families was also investigated; so thoroughly was the social work done that 93% of the sample coöperated. The striking finding was the regular association of higher fertility with every kind of social inefficiency observed. Thus while the average number of living children in the normal working-class families was 3·38, the average number amongst families containing a mentally defective child was 4·69. The difference would have been even greater but for the effect of differential mortality, for while in the normal families an average of 0·74 children had died, in those containing a mentally defective child the mean number of deaths was 2·47. While families containing a socially inefficient child had a higher fertility than the controls, the highest fertility of any group investigated was in the families containing a delinquent child. The data revealed clearly the difference between high-grade and low-grade mental deficiency, the former tending to come from lower social classes; and although few of the parents were classified as mentally defective many of the parents were mentally "subnormal." Another comparison showed that while 39% of the heads of normal families were graded as unskilled labourers, 63% of fathers of children attending special schools fell into this category. Amongst those unemployed for 2 years or more, and among the chronically destitute, 90% were married, compared with 74% in the normal working-class sample. Mr. Caradoc Jones concluded that, broadly speaking, low intelligence of parents is associated with high fertility and defects of all kinds amongst the children.

HIGH-GRADE DEFICIENCY AND DIFFERENTIAL FERTILITY

Dr. J. A. FRASER ROBERTS described the distinction between high-grade and low-grade defectives. The latter are the dwarfs of mental stature owing their condition to a variety of special causes, some genetic, some environmental, while the former are no more than the tail-end of the normal curve. The dividing line between mental deficiency and dullness is purely arbitrary. Mental deficiency cannot be equated to the Binet intelligence quotient (I.Q.), though of course the relationship is close. There is a level below which care and control are practically inevitable; above this is a wide band in which the need for care depends on social maladjustment coupled with intellectual retardation; of these two factors, the I.Q. level can be studied the more easily. In a survey of school-children carried out at Bath before the war it was found that the brightest 4% had an average of 1·70 living sibs, the median 4% had 2·78, and the dullest 8% had 3·72; when allowance was made for uncompleted families the figures became respectively 1·95, 3·51, and 5·03. These results illustrate the typical linear relation between intelligence and number of sibs, the latter falling steadily as the former increases. Although on the average the lower the parents' intelligence the lower is that of their children, actually the bulk of children with I.Q.'s below 70 come from the dull and backward since these are so much more numerous than those with I.Q.'s below this level. Such observations permit an indirect estimate of the expected fall in the mean intelligence of the population; on the data quoted, after allowance for additional factors, this amounts to nearly 3 points of Binet I.Q. per generation. This estimate is, as Sir Cyril Burt lately suggested, too high; but even a fall of 1·5 points would mean an increase in the frequency of those with I.Q.'s below 70 from 2·1% in 1950 to 3·3% in the year 2000, with a corresponding loss of the very gifted. The discrepancy between the indirect estimate of the decline and what Professor Burt has called the direct evidence may be due to several factors, which may also affect in other ways the estimates of very low I.Q.'s in future years. First of these factors is the influence on intelligence of the mother's age or the order in the family; if this influence were large it would account for a considerable exaggeration of the estimated decline. Secondly, greater mobility has meant that people marry those less closely related to them. If genes making for higher intelligence happened to be more usually dominant, then the average intelligence of the population would rise; this would not represent a real gain of good genes but simply their arrangement in a more useful order. Thirdly, mobility helps people to find mates more like themselves, particularly in regard to intelligence. The result is to increase variability; while the average for the population is not changed, there are more very bright and more very dull, so that the expected numbers of I.Q.'s below 70 will be increased, though there will be compensation at the other extreme. Finally, a relatively low intelligence, if coupled with emotional and temperamental stability, may be compatible with a useful place in society. Although the frequency of low intelligence is likely to increase substantially, there may, owing to advances in knowledge, be no such corresponding increase in those requiring care, supervision, and control.

DISCUSSION

Several speakers, while admitting that it was difficult to advance precise arguments for optimism, expressed confidence that counterbalancing forces would avert the threatened decline. Dr. E. O. LEWIS felt that it might be the cultural component in test-results which was specially concerned. Dr. T. A. H. MUNRO, however, held that if it was admitted that the dull were more fertile and intelligence was to some extent inherited, then at least some decline was inevitable; he reinforced Dr. Blacker's plea for better statistics of mental disease. Dr. W. G. MASEFIELD asked whether differential fertility had not been operating for a long time; if so, must not all the Elizabethans have been geniuses?

In reply, Dr. ROBERTS said that while it was probable that differential fertility had operated for a long time, until the decline in the European birth-rate about 1870 it was on a much smaller scale and might have been more than neutralised by differential mortality amongst the young. It was probably only since family limitation became so widely practised by the more intelligent that the process had assumed its present alarming proportions.

"... The maintenance of intellectual integrity, the defence of intellectual liberty, the cultivation of strict veracity and methods of precision, the sharing of new knowledge, the obligation to publish important findings and to include essential references, and the recognition of priority where priority is due—all these are a part of the discipline, in an ethical regard, which men of science observe. ... In common with other men of science, doctors must shortly decide whether they are willing to comply with Governmental insistence on secrecy in fundamental researches ... [and] whether they are willing to accept a similar demand for secrecy ... by industrialists engaged in the production of things necessary to medicine and human welfare. Of intellectual standards, the Hippocratic injunction states succinctly: 'One must occupy oneself with facts persistently' (*Precepts*), and 'There are, in fact, two things, science and opinion; the former begets knowledge, the latter ignorance' (*Law*). As a reminder for the teaching of the clinical schools the latter sentence might suitably be inscribed above the portals of each ward and lecture-room."—Prof. J. A. RYLE, *Brit. med. Stud. J.* Spring Term, 1947, p. 3.

Reviews of Books

Child Treatment and the Therapy of Play

LYDIA JACKSON, B.SC.; KATHLEEN M. TODD, M.B., D.P.M. Introduction by Emanuel Miller, F.R.C.P. London: Methuen. Pp. 110. 8*s*. 6*d*.

A BOOK on play therapy has long been overdue, but here is one describing the rôle of play in the treatment of problem children, rather than a work on the technique of play therapy. The authors plead for a wider use of common-sense ways of adjusting family life; and the connexion between maladjusted parents and unhappy children is clearly shown. Play in children can serve as an outlet for the "reactive-personality" produced in the child—reactive, that is, to environmental difficulties and to emotional strain, whether applied from without or developing within. Regressive play, obsessional behaviour, and the typical hyperactive and scattered play of the unstable child are signs of conflict. Play as treatment may be a cathartic for disturbed emotions; or the child may relive, with the therapist, earlier experiences which have lacked a sense of fulfilment. The rôle of the therapist is indicated, but no clear directions are given on methods of dealing with some of the situations; and though to use description rather than interpretation is to avoid dogma, it makes the book a little dull in places.

Le bacille de Koch dans la lésion tuberculeuse du poumon

G. CANETTI, chef de laboratoire à l'Hôpital Cochin; assistant a l'Institut Pasteur. Orleans: Flammarion. Pp. 168.

L'allergie tuberculeuse chez l'homme

G. CANETTI. Orleans: Flammarion. Pp. 338.

THESE two works together form a treatise on the pathogenesis of the tuberculous lesion, one volume dealing with the lesion, the other with the immunological reaction. Dr. Canetti has not had access to some of the new work published since 1940, and this has deprived him of the help of Prof. Arnold Rich's monumental work which appeared in America in 1944 and covers much of the ground in greater detail. Nevertheless, he is well read in his subject, and has studied primitive tuberculosis extensively in Cochin, where he was head of the hospital laboratory service. He makes a valuable contribution to this neglected aspect of the subject.

In the first book he sets out to study the *Mycobacterium tuberculosis* in its setting in the pulmonary lesions, claiming with justice that much of the work on the pathology of tuberculosis in the past has been one-sided —a study either of the bacillus or of the lesion. His work is based on the investigation of 1500 necropsies on cases of pulmonary tuberculosis, supported by sections of the experimental lesion; and he sets out the therapeutic implications of these studies. He appears to regard caseation as the key to the evolution of the tuberculous lesion, following Huebschmann in placing it early in development, immediately after exudation and before the cellular phase or follicular reaction; but he does not deny that caseation may also follow the latter, as postulated by most pathologists.

He uses an interesting new technique, estimating the number of bacilli per field of the microscope in stained sections—the method which Gaffky first applied to the direct film examination of sputum. By means of a large series of such bacterial section counts he has determined the relative number of bacilli in the different types of lesion. In sclerotic areas the number was extremely small, while in liquefying caseous areas the bacilli were uncountable; in areas of solid caseation, however, they were relatively scarce. A series of cultures were also made to compare the number of viable bacilli with the total of acid-fast organisms counted in the sections with this technique. There are, of course, obvious difficulties in an investigation of this nature and a generous allowance must be made for unavoidable errors, but they are probably of the same order in most instances.

The differences noted in the various types of lesion—follicular, caseous, fibrocaseous, sclerotic, and cavernous —lead on to a discussion on the relative immunological value of these lesions. The caseous lesion is the critical one, and this is discussed at some length. Whatever the biochemical factors which enter into its production, it is regarded as an outward and visible sign of hypersensitivity.

In the second book he follows accepted views in recognising that allergy and anaphylaxis constitute different reactions; and he is concerned, of course, with the former. More than half the work is devoted to an account of allergy as seen in the tuberculin reactions obtained in 4600 patients tested.

The results are classified to show the differences of age, sex, and nutritional state. In latent tuberculosis, graphs are reproduced to show that the percentage of negative reactors steadily declines from the 15–20 to the 40–50 age-groups, and then rises again to the 70–80 group. Strongly positive reactions are more common in women than in men at all ages. Poorly nourished subjects tend also to give stronger reactions. An interesting comparison is also made between the positive reactions of different clinical types of tuberculosis, and the results are classified in three groups. The strongest positive reactions are found in the cases of cutaneous, lymph-gland, and osseous tuberculosis, and the feeblest in peritoneal, pleural, and genito-urinary types of the disease. Between these two groups is an intermediate one comprising the various stages of pulmonary tuberculosis.

A section on the relatively new Von Groer technique of allergometry with tuberculin shows that pleoergy is the general rule in cases with good resistance and *pleoæsthesia* in patients with advancing disease. The last three chapters of the book deal with the mechanism of tuberculous allergy and its relation to the clinical progress of the disease and to immunity, and here Dr. Canetti's long and critical analysis of Ranke's three stages is telling. That theory was always too facile, and the auth sets forth its defects in full.

Anesthesia in General Practice

STUART C. CULLEN, M.D., head of division of anesthesi logy, department of surgery, State University of Iow Hospitals. Chicago: Year Book Publishers. London H. K. Lewis. Pp. 260. 19*s*. 6*d*.

THERE are now many textbooks on anæsthetics. Som cater for the D.A. candidate: material well systematise text comprehensive, facts stated concisely. Others a written for the undergraduate, giving him a groundi in the simple fundamentals of the subject. Dr. Cullen book will appeal to both: it is accurate and scholarl if not comprehensive, and it deals with fundamentals, perhaps not very simply. In his choice of topics he h the needs of the occasional anæsthetist in view. H writes well on airway, inhalation agents and techniqu spinal anæsthesia, shock, pre- and post-operative trea ment, regional anæsthesia, oxygen therapy, and explo sions. He also discusses the use of curare, in which he has great personal interest. This drug, though at present beyon the scope of the general practitioner, is now in the spot light of publicity, and its inclusion in the book is welcome

Diseases of Blood-forming Organs

in the light of Biopsies of Marrow, Spleen an Lymph-nodes. Dr. JULIAN ALEKSANDROWICZ. Cracow Friedlein. Pp. 265.

IN this Polish monograph are set out the author' views on the anatomically connected but functionall separate myeloid, lymphoid, and reticular tissues. H studied them, in health and disease, by simultaneou biopsies of marrow, spleen, and lymph-glands, and h has heterodox and interesting ideas on the classificatio of the various blood and tissue cells belonging to thes three groups. He places plasma cells with monocytes i the reticular group, and myeloma he classifies as "plasmocytic reticulosis." Ferrata cells he regards as mature reticulum cells. He has some experiments to show tha the production of megalocytic red cells depends o physicochemical plasma factors like heparin concentration and carbon-dioxide partial pressure, and not onl on the presence of megaloblastic erythropoiesis. Th illustrations, both coloured and monochrome, are no very clear and sometimes inaccurate. This book wa produced under difficulties during the German occupation and we hope that, now conditions are easier, the autho will publish a summary of his ideas in French or English.

Messrs. Kegan Paul inform us that the price of O. Fenichel's PSYCHO-ANALYTIC THEORY OF THE NEUROSES (*Lancet*, March 22, p. 372) has been altered to 40*s*.

Vitamin Therapy—its uses and limitations

"Fitness for purpose"— the test of design

Whether the subject be motor-cars, silk stockings, surgical instruments, or pharmaceutical preparations, the "designer" of today applies *one* criterion—"fitness for purpose."

How should this criterion be construed in the case of dietary supplements? It is submitted that the following points are relevant.

1 Does it contain the most important vitamins and minerals? ✓
2 Are the quantities related to bodily requirements? ✓
3 Is the dose convenient? ✓
4 Is the cost such that the physician's directions will be followed? ✓
5 Are additional supplements unnecessary? ✓

The "fitness for purpose" of the two Vitamins Limited's supplements described below may readily be verified by reference to the abovementioned criteria.

COMPLEVITE

A *single* supplement for *multiple* deficiencies

The recommended adult daily dose provides :

vitamin A	4,000 i.u.	vitamin C	20 mg.	iodine	not less than 10 p.p.m. each
vitamin D	300 i.u.	calcium	160 mg.	manganese	
vitamin B$_1$	0.6 mg.	iron	68 mg.	copper	

20 days' supply (120 tablets) 5/-

PREGNAVITE

A *single* supplement for safer pregnancy

The recommended daily dose provides :

vitamin A	4,000 i.u.	vitamin E	1 mg.	iodine	not less than 10 p.p.m. each
vitamin D	300 i.u.	nicotinamide	25 mg.	manganese	
vitamin B$_1$	0.6 mg.	calcium	160 mg.	copper	
vitamin C	20 mg.	iron	68 mg.		

20 days' supply (120 tablets) 6/-

Complimentary carton of either Complevite or Pregnavite gladly sent on request.

Social Pathology

To the universities it must be both flattering and frightening that in an unstable society so many of the pioneers and the planners turn to them for help. The help asked is seldom just guidance or information: more often the universities are desired to do a job themselves or train the workers for it; and always the implication is that they are more competent or more disinterested than anyone else.

In his address on March 6, as principal guest at the centenary meeting of the New York Academy of Medicine, Prof. J. A. RYLE, of Oxford, put the case for the academic status of social medicine. He drew a pattern of analogies between individual medicine and individual pathology on the one hand, and social medicine and social pathology on the other—meaning by social pathology the study of the relation between social conditions and individual disease. Tracing the development of social pathology, from FARR and CHADWICK forward through the achievements of public health and sanitary science, he showed that its methods are observational and latterly in some degree experimental: in observation it uses statistics and planned sociomedical surveys; in experiment it can sometimes study comparable groups of people in partially controlled conditions, as when half a slum population is rehoused on an estate and its health deteriorates because the food it can afford is less. "Individual pathology deals with the quality and effects of diseases, and, in practice, assists diagnosis and treatment, while social pathology deals with the quantity and cause of diseases, and, in practice, assists prevention." Individual pathology is well ensconced within the four walls of the medical school-cum-hospital, but social pathology has hitherto been pursued by the public-health departments or by special institutes, remote in space and often in spirit from university and hospital life.

For two sets of reasons it is now desirable, in RYLE's opinion, that social pathology should come into the university group. In the first place, its own outlook is changing. Its interest is expanding beyond the old concern with infectious diseases and the mechanical environment of man. It now considers all the effects of community life on the health of the individual—nutrition in its various aspects, economic circumstance, educational influences, and the whole psychological pattern of human relationships. These, it finds, act very differently on different individuals; they show much less uniformity of effect than do contaminated water-supplies or epidemics of smallpox. Social pathology can no longer treat its human material as all of a kind; simple arithmetic gives place to complicated statistics, and even these are inadequate. Social pathology must therefore sit down alongside the physicians who study individual patients, the almoners and social workers who study their homes and families, and the psychologists who have some faint clue to the complex of emotional relationships involved.

In the second place, the outlook of social pathology is needed within the medical school as a corrective to the narrowing tendency of hospital medicine. Wards full of patients admitted because their diseases are dangerous to life, difficult to diagnose, or merely interesting through their rarity: these are the stuff of medicine to the student and the teaching physician. Superimpose that selection on the mass of handicapping disease in the community: the peptic ulcers, the rheumatic diseases, the upper respiratory infections—and they scarcely overlap. What too does the ward know of the domestic upset that has resulted from, or has brought about, the illnesses that it does study? How little the specialist physicians, in contrast with the general practitioners, are acquainted with the lives their patients lead and the places where they lead them! The student's perspective is distorted in the ward atmosphere of intensive, largely mechanical, investigation, in which the minutiæ and the rarities of disease receive so much attention, and its human significance so little. True, the latter is all too evident when the student reaches practice; but by that time his mind is cast in the mould his teachers have given it, and a cardiac murmur will always seem to him more important than an over-possessive mother. RYLE sees the hope that the organised study of social pathology, introduced into the curriculum and into the teaching hospitals, will give a broader and more humanistic outlook to the emerging doctors, and fit them better for their important rôle in a changing society.

That is, in outline, his main thesis; and with his aim we are in full sympathy. The importance of the opportunity that the new era offers to medicine cannot be exaggerated; and "new era" is not too big a term, for the whole structure and working of society is changing under our eyes with bewildering speed. Yet our faith is that the new society must still serve, not rule, the development of the individual—his health in the fullest sense. The doctor is his adviser in this matter, and the doctor must also become society's adviser in the same matter. Hence the need for an altered emphasis in the doctor's training. Of the method of securing the alteration, however, we are less sure. RYLE seems to picture public health, with a new inspiration, entering and reforming the medical school. But, if we read him aright, it is still the health of the individual which is paramount, though now to be studied against a wider background; and if so the task is surely for those to whom the individual has always been the focus of interest. Should not social "pathology" and social medicine grow out of hospital medicine rather than from traditional public health? They will no doubt require some of the public-health techniques, such as field studies and the application of statistics; but, unless the new development is based on the physician's training and the physician's prime concern for the individual patient, it will be in danger of serving a wrong philosophy, of becoming a science of herd management. Here we set store by RYLE's own example. His friends rebuked him for leaving the clinical fold. He replied, "I have merely taken the necessary steps to enlarge my field of vision and to increase my opportunities of ætiological study. My allegiance to human medicine is no whit broken." There must be many younger physicians willing to follow that lead, especially in the freer atmosphere which they can hope to find in the new health service. To them we look, in collaboration with their expert colleagues in public-health departments and in laboratories, to play a major part in adapting the study and teaching of medicine to the needs of an industrial society.

Source of the Red Cells

PRESENT ideas on the origin of the red blood cells are still based on the work of DOAN, CUNNINGHAM, and SABIN[1] published twenty-two years ago. They depleted the bone-marrow of pigeons by feeding them on a poor diet, and of rabbits by injecting emulsions of typhoid bacilli, and then watched the regeneration process. They found that the first phase of the red cell arises by division from the endothelium of the intersinusoidal capillaries—the small blood-vessels connecting the larger sinuses that make up the vascular system of the marrow in birds and mammals. From this first generation, hæmoglobinated erythroblasts arise by mitosis and development of hæmoglobin in the cytoplasm; and these cells, pushing into the capillary cavity, dilate its lumen and stretch its wall. The capillary all this time remains closed, and DOAN did not think that it normally opens to the circulation until the nuclei of the erythroblasts have disappeared and the red cells are mature; NIZET,[2] however, has recently produced evidence that red cells are discharged from the marrow in the reticulocyte stage and finally ripen in the circulating blood. In hyperplastic marrows, when there is an exceptional demand for red cells, the capillaries open before the red cells reach the reticulocyte stage, and then erythroblasts at various stages of development are swept into the blood-stream. Unfortunately, DOAN and his co-workers used a technique that was not really adapted for the differentiation of stages of erythropoiesis, since this depends on nuclear rather than cytoplasmic changes. Worse still, they used the name "megaloblast" for the first phase of normal red-cell development, forgetting that this name had been used in Europe since EHRLICH's time for a pathological cell found in pernicious anæmia; so when DOAN's ideas were applied to human pathology they led to a serious confusion which affects some American writings to this day. This confusion has obscured the fundamental value of DOAN's observations on the intravascular development of the red cells.

Since 1925 others have entered the field and proposed other modes of development. Some say that the lymphocyte can transform itself into an erythrocyte. DURAN-JORDA[3] maintains that the red cell is a product of cellular secretion; at first he thought that the plasma cell disintegrates to form a red cell, and the nuclear remnant, with a halo of cytoplasm, becomes the normoblast. Later[4] he propounded an alternative theory that red cells are formed from the granules of the polymorphonuclear eosinophil leucocyte: the cell increases in size, develops about 200 red corpuscles in the cytoplasm, expels them, and ends up as a lymphocyte. These views have not so far been confirmed, and the last is open to the objection that degenerating cell forms were being observed. WADJA[5] has described changes in muscle fibres degenerating after injury which suggest that in the injured fibre the sarcomeres become transformed into erythrocytes; the fibre is changed, in effect, into a red-cell-containing capillary. WADJA does not suggest that this is the sole source of the red cells, but proposes muscle as an additional source, and quotes some interesting parallels from comparative anatomy. These observations are purely cytological, but, since injured muscle is involved, it should be possible to devise a means of obtaining and counting the red cells formed in this way. Both DURAN-JORDA and WADJA lay stress on the difficulty of explaining the fate of the nucleus of the normoblast; FIESCHI and ASTALDI,[6] watching the process in vitro, have shown that it is got rid of by expulsion, fragmentation, or lysis, expulsion being the usual method.

It cannot be said that any of these theories offers a serious challenge to the accepted view that the bone-marrow throughout the body is the source of the red cells. No-one who reads the history of medicine would denounce them off-hand because they seem bizarre, but they clearly need more confirmation—why, for instance, does muscle-tissue hæmopoiesis not appear when the bone-marrow fails, and why does extramedullary hæmopoiesis, when it occurs, favour other tissues? Still, they remind us that the subject, like many others in medicine, is still open. We hope that new information will be sought along physiological lines, or by studying cytological changes paralleled by changes of function; no-one wants to see a return to the sterile morphological controversy that makes up so much of the German writings on this subject.

German Drugs

UP to about 1936 most of the new synthetic drugs were a product of German chemical skill and pharmacological enterprise. For many years it seemed hopeless for British science or industry to compete in this field. But since 1936 the tables have been turned and the chief advances have come from Britain or America. The military occupation of Germany has enabled us to examine the inner working of the once admired and feared German pharmaceutical industry and to study its methods and secrets; the results of these investigations have been published in a series of reports by the British and Combined Intelligence Objectives Subcommittees (BIOS and CIOS).[7] The picture gained from these reports is somewhat unexpected. German chemotherapy, which once led the world, is now lagging behind in some important respects. Speaking generally, the work of the synthetic organic chemists has been of a very high order, but their new compounds have been much fewer than propaganda had led us to believe; the biological testing of these new compounds in the laboratory has been adequate, though it has not kept up with recent advances in Britain and the United States; the clinical testing of products found active in the laboratory has often been surprisingly bad and promising new compounds, such as antimalarials, have been unprotestingly dropped because of an unfavourable clinical test conducted in haphazard fashion on two or three patients. Moreover the initial successes of the German workers, assisted by skilful propaganda, had produced an exaggerated conception of the scale on which these researches were done. About two-thirds of the new products come from a single centre, the research laboratories of the I.G. Farbenindustrie at Elberfeld, and the graduate staff employed there in the search for new remedies numbered only 26 chemists and 11 medical or biological workers.

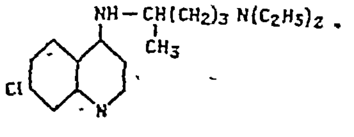
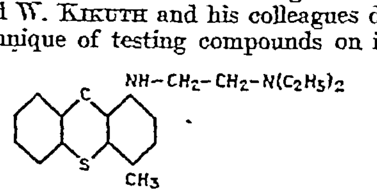
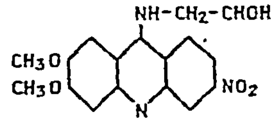
War-time German research has produced nothing to compete with penicillin, streptomycin, 'Paludrine,' and the numerous sulphonamides introduced by Anglo-American work. The best-established German compound of the war years is the sulphonamide, 'Marfanil,' $NH_2.CH_2.C_6H_5.SO_2.NH_2$. supplies of which were captured in North Africa and submitted to in-vitro and clinical tests[8]; these showed it to be useful as a local application to wounds but largely inactivated in the blood-stream. In the antimalarial field, which had long received much attention from German workers, the showing is better. They had discovered a variety of compounds which were highly active in bird malaria, including phenyl-substituted dialkyl amino - alkyls ('Dimeplasmin'), sulphonamides ('Bemural'), and 3-alkyl quinolines ('Endochin'). Unfortunately (as with many compounds discovered in the U.S.A. and Britain), this activity was not confirmed in human malaria. With one series, the 4-amino quinolines, they were more fortunate; and during the early part of the war one of these compounds, 'Sontoquin,' was given small-scale clinical trials at Hamburg and elsewhere. A batch of this preparation was sent to North Africa in 1942 for field trials and was captured by the Allied forces in Algeria and Tunis. The whole series was exhaustively explored on a much larger scale by American workers, who finally selected one member—'Resochin,' 'Chloroquine,' 'SN 7618'—as the best for general purposes. This seems to be superior to quinine or mepacrine, but it is doubtful whether it will prove as good as paludrine, and it will certainly be less cheap.



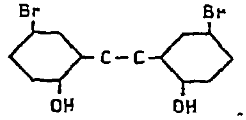
The Elberfeld staff showed particular enterprise in the search for new remedies against schistosomiasis, and W. **Kikuth** and his colleagues developed a new technique of testing compounds on infections of *S. mansoni* in mice. Therapeutic activity was discovered in an entirely new class of synthetic compounds, synthesised by **Mauss**, and the best member of the series, 'Miracil,' is very effective against experimental infections in mice and monkeys. It is hoped to give this compound a clinical trial under British auspices.



In view of the importance of typhus in Eastern Europe, great efforts were made to discover an effective chemotherapeutic remedy for rickettsial infections. The most promising compound discovered was 'Rutenol,' a chemical salt of three parts arsenic trioxide with two parts of a nitro-acridine derivative. This compound is effective in the treatment of mice infected with *R. mooseri*. Its discoverer, **Fussgänger**, also claimed that it was effective in human cases of epidemic typhus or Wolhynian fever, but the tests lacked proper controls, and in the two years since the German claims became known to Anglo-American workers there has been no confirmation of its clinical efficacy. It is unlikely to be as valuable as *p*-aminobenzoic acid in rickettsial infections.



Another substance for which the Germans made big claims is dibromsalicil, developed by **Richard Kuhn**, a former Nobel prizewinner, at Heidelberg. This and other salicyl derivatives prevent the growth of bacteria in vitro and have had some success as local applications to infected wounds. But there has been no confirmation of their value outside Germany and it seems improbable that they will compete with penicillin and streptomycin.



A Great Physiologist

PHYSIOLOGY is not so much a subject as a point of view; and Sir **Joseph Barcroft**, if he did not explicitly preach this text, lived it. The genius of simplicity brought him to the heart of the most complex problem, and the use of this gift earned him a place among the great physiologists. Whatever he touched fell into perspective and was illuminated—illuminated so clearly and with such a delightful play of wit and simile as to reawaken the fascination of discovery in the most disillusioned. He was not a specialist, but brought his zest for scientific adventure to the exploration of many fields—the physiology of the blood, the spleen, the kidney, the fœtus, and the processes of ruminant digestion. He was not a hacker of the jungle, but made rather for the peaks; he seemed to delight in showing others the view, and to be on the lookout for those who could see it as he did. He did not pretend to know what was in each valley, but his recruits were there and rarely failed to find something worth while. His *Architecture of Physiological Function* was an attempt to find for physiology as a whole that coördinating central idea which he had revealed in so many of its parts. His interest latterly in the physiology of the fœtus represented, perhaps, a final effort to come to closer grips with the fundamental mystery. With his passing, a spiritual link with the great period of English physiology has dissolved.

Annotations

FUTURE OF GENERAL PRACTICE

"How can we modify this Act to preserve more of the past of general practice?" has been the loudest question lately in medical gatherings. It is refreshing to turn to Prof. Robert Platt's remarks on the future of general practice, made in a recent address.[1] He looks to the Act, and to the profession operating it, to make possible great improvements. He has the courage to say "there is a great deal wrong with general practice," and to list its faults. The doctor has insufficient time to do his job well. He works too much in professional isolation. There is no recognised standard in general practice; that is to say, a practitioner's work is so screened from the eyes of his colleagues that he lacks the stimulus of knowing that it will be judged. He complains of an inferior status vis-à-vis the specialist. Finally, he has not been trained on proper lines.

The Act is capable of adjusting the numbers of doctors to the amount of work that is to be done in a way that "private enterprise" never did. Platt sees no harm in basic salary combined with tapered capitation fee as a means to that end. In the health centres there is a remedy for professional isolation; a doctor will talk shop, with mutual advantage, to another doctor in the same health centre, where he would, for prestige' sake, have remained silent in the presence of a competitor, and he will know that at any time his case-records may have to be made available to his colleagues. These are powerful and unbureaucratic encouragements to maintaining a high standard of work.

The status difficulty has its roots in the bias of medical education. Platt holds it ridiculous that the practitioner of the future is trained wholly by the specialist. Surely he is right. Even if the content of this training were altogether appropriate, the respectful student could not help emerging from it with the impression that specialists are a superior order of beings. So they are, in some respects; but mostly they are not, in others. If the teaching staff included some competent general practitioners, broad in their outlook and wise in their experience of men, able to look the specialists in the face and prick their bubbles on occasion, the student's perspective would be truer, and the short-sighted stampede of the young into specialism would cease. To this end Platt offers the same suggestion as we did[2]—namely, that one or more health centres should be established as an integral part of every teaching school. The members of their staffs should be chosen for their ability to conduct general practice well, and for their capacity to teach the students who (singly for preference) would accompany them throughout their working day. We can think of no single innovation which could do more than this to raise the standard and realise the true function of general practice in the next generation.

BLOOD-FLOW IN BONE

THE failure of their many attempts at obtaining arteriograms of bone vessels in living subjects led Lamas and his colleagues[3] to investigate the intra-osseous circulation. They argued that a relatively slow blood-stream would be expected because none of the three physiological functions of the long bones—mechanical support of the body, storage of calcium salts, and hæmopoiesis—need a rapid circulation; hæmopoiesis and calcium storage are in fact facilitated by a slow blood-stream. Nor does movement of a bone, unlike that of muscle, require an extra supply of blood. When a dye was injected into the external iliac arteries of dogs they found that it took four seconds to reach a wound in the foot, seven seconds to reach the skin, and a whole minute to reach the bone-marrow (none reached compact bone). On the other hand, the dye was removed much more quickly from the marrow than the soft tissues; in less than three minutes it disappeared from the marrow, whereas it was visible for ten minutes in the skin. Studying the minute anatomy of the long bones they found that the nutrient artery describes many curves before entering the bone, and, after dividing into ascending and descending branches which run through the marrow, it ends in wide blood-spaces close to the epiphyses; these blood-spaces are in close contact with veins of wide calibre and very thin walls. This arrangement of blood-vessels reduces the pressure and speed of circulation in the arteries, and enables the veins to carry substances quickly away from the blood-spaces—hence the efficacy of therapeutic injections into the marrow. The slowness of the flow through the nutrient arteries is supported by the plethysmograph measurements of blood-flow in the normal humerus made by Edholm et al.[4] From their figures it is estimated that the amount of blood normally flowing through the whole skeleton probably does not exceed 100 c.cm. a minute, though it may be vastly more in Paget's disease.

Though all the long bones have a highly efficient venous drainage, the sternum is the bone of choice for transfusions and infusions because of its convenient situation, because it has excellent short venous connexions, through the internal mammary and innominate veins, with the superior vena cava, and because the compact part of the bone is very thin and easily pierced with the needle, the site of election being the upper part of the manubrium. The firm anchorage that the sternum gives for the needle was found useful in North Africa, where wounded were transported long distances with an intrasternal drip-transfusion running. It can also be made use of in the continuous administration of penicillin. Thus Giraud and Desmonts[5] injected 20,000 units of penicillin, in 250 c.cm. of serum, in two hours by this route, and two days later gave 40,000 units in 250 c.cm. of serum in five hours without encountering any difficulties.

ADSORPTION OF ENDOGENOUS TOXINS

FEW now believe that the various toxic chemicals, such as indole, skatole, tyramine, guanidine, putrescine, &c., formed by the decomposition of protein in the large bowel cause systemic disease or even the symptoms associated with constipation, though it has lately been suggested that their action may be partly responsible for the degenerative changes of old age. Most prefer to think that the barrier offered by the bowel wall and the detoxicating action of the liver together form an efficient protection against intoxication.[6] Nevertheless, since the substances are responsible for the unpleasant odour of fæces, their removal would be a great blessing to patients who are incontinent or have an artificial anus. Kaolin and activated charcoal have been much used for the purpose, but neither has provided the complete answer.

The ideal adsorbent should be completely effective in removing odour but should not interfere with intestinal synthesis of vitamins or with the absorption of foodstuffs and drugs. Martin and Wilkinson[7] tried to find a suitable adsorbent which will adsorb the toxic chemicals in the pH range of the gut. They found that 'Amberlite IR-4,' a synthetic resin, was very effective against indole and skatole, while all the amines tested (putrescine, cadaverine, tyramine, histamine, and guanidine) were strongly adsorbed by activated permutite. Kaolin, in their opinion, "cannot compare with permutite as an adsorbing agent for amines"; they also found that it adsorbed no skatole. These in-vitro results were supported by toxicity experiments on mice, in which the toxic compound was given alone to one group and also to a group which received the adsorbent at 10% of the basic diet. The results clearly showed the effectiveness of the adsorbing agents in counteracting the toxicity of these putrefactive chemicals. Thus the death-rate resulting from a dose of 0·4 g./kg. of indole was reduced from 50% to 20% by the inclusion of 10% amberlite IR-4 in the diet and from 50% to 10% when another 5% of amberlite IR-4 was given in suspension. Permutite given in the same amounts reduced the death-rate caused by 0·5 g./kg. of guanidine acetate from 50% to 20%.

The possibility of interference with vitamin absorption from the gut was clearly borne in mind by these investigators. They reported in another paper [8] that amberlite IR-4 does not adsorb aneurine or riboflavine at the pH of the human stomach or intestine and that vitamin C, though strongly adsorbed at an acid pH, is again completely desorbed at the higher pH of the intestine. In addition, rats showed no signs of nutritional deficiency when amberlite IR-4 or permutite were fed at 5% levels. In this connexion Melnick et al.[9] have shown that fuller's earth reduces the availability of vitamin B_1, while kaolin does not.

Whether amberlite IR-4 or permutite is superior to activated charcoal remains to be seen, but it seems likely from these experiments that a multiple adsorbing agent could be devised which would prove more effective in the adsorption of putrefactive substances from the intestinal tract than those now in clinical use.[10]

MANUAL REMOVAL OF THE PLACENTA

THE cautious attitude of British obstetricians to manual removal of the placenta has been based on a lively fear of "obstetrical shock" and intra-uterine sepsis. There was good reason for this attitude two decades ago, when there was no chemotherapy and blood or plasma for transfusion was not immediately obtainable. Even with these safeguards, however, the risks of manual removal have not disappeared. According to Sewall and Coulton,[11] this is because manual removal has only been employed when the patient is already shocked and anæmic; and they attribute the bad results of the operation to the bad timing of its performance. They support their view by recording 45 consecutive manual removals under their own or their residents' care in which the mortality was zero and only one patient, already suffering from bronchitis and pyelonephritis, gave rise to anxiety. No special technique was used, and the indications for the operation were blood-loss in 15 cases, expected blood-loss in 22 cases, and retention of the placenta in 8 cases. Chemotherapy was employed in 22 cases. Shock was absent in the whole series, though what is described as subclinical shock was noted in 3 cases.

The average time from the beginning of the third stage until manual removal was performed was 8 minutes in the cases undergoing manual removal for blood-loss, and 14 minutes where the removal was done prophylactically for fear of blood-loss. In other words, these workers waste no time in manually removing the placenta. They urge that Credé's expression should not be persisted with too long. Protracted and vigorous attempts at Credé's expression are extremely liable to cause shock, and Sewall and Coulton think they also make subsequent manual removal hazardous. They therefore use a trial expression once. If this is not successful, they wait for 20 minutes and repeat it; and if the second attempt fails the placenta is removed manually. When there is bleeding, manual removal is used much more quickly. In 5 cases the uterus was packed; and it is claimed that packing does not increase morbidity—with prophylactic sulphonamides, of course.

Forty-five swallows do not make a summer, and the enthusiasm of these Massachusetts workers is not likely to change our more conservative attitude; but their experience does strongly support their view that if manual removal is going to be employed it should be resorted to more quickly than it has been in the past. In a fit woman not yet suffering from the effects of blood-loss it is a relatively simple operation. In a shocked and anæmic woman it is hazardous and possibly lethal, and its morbidity may well be attributed to the poor state of the patient rather than to the inherent vice of the operation.

"HOME" OR HOME?

NOBODY would wish to deny that many homes managed by voluntary societies achieve a high standard in the care of children deprived of a normal home life. A memorandum submitted by the National Council of Associated Children's Homes[1] reminds us that some 40,000 children—nearly half the homeless children in the country—are in the care of voluntary homes and hospitals, and that many approved schools, foster-homes, and remand probation homes are also administered by the voluntary societies.

In discussing the several methods of caring for such children, the council's opinions are noticeably at variance with the Curtis report. They agree that each child's case must be considered on its merits, but think it dangerous to assume that adoption is in the main better than boarding-out, or boarding-out than community residence, or that community residence is better than either. About adoption they hold highly cautious views, hinting at "unforeseen developments arising later from unwise upbringing or incompatibilities of temperament." In their opinion "adoption will not prove an adequate solution of the problem of the homeless child." They are equally dubious about the advantages of boarding-out: "at its best boarding-out for the homeless child is but a partial solution of the problem. Some of the responsibilities of child care are inescapable and cannot be contracted out." They believe that there will always be a "large residuum for which some other arrangements must be made." The section on the voluntary homes, however, presents this method of dealing with children in its most favourable light: the drawbacks emphasised by the Curtis Committee—the lack of a strong personal relationship with an adult, for individual children, and the depression of responsibility and initiative associated with institutional life—are not mentioned. Light is focused strongly on the admitted advantages of the homes: the good food, comfortable quarters, the devoted staff.

These opinions, of course, must carry weight since they are so well sponsored; and it is easy to realise how strongly the sight of groups of happy well-nourished secure children must affect the judgment of those who wrote it. Nevertheless, material nourishment does not make up to the child for the absence of personal love, and even security may be bought too dearly if it hinders development of initiative. The alarm the council express at the risks of adoption are surely far-fetched: even in happy families, born to each other's society, unforeseen developments arise from unwise upbringing; nor are incompatibilities unknown. But what the family gives is something few people would willingly surrender for the care offered by even the best voluntary home.

Annotations

FUTURE OF GENERAL PRACTICE

"How can we modify this Act to preserve more of the past of general practice?" has been the loudest question lately in medical gatherings. It is refreshing to turn to Prof. Robert Platt's remarks on the future of general practice, made in a recent address.[1] He looks to the Act, and to the profession operating it, to make possible great improvements. He has the courage to say "there is a great deal wrong with general practice," and to list its faults. The doctor has insufficient time to do his job well. He works too much in professional isolation. There is no recognised standard in general practice; that is to say, a practitioner's work is so screened from the eyes of his colleagues that he lacks the stimulus of knowing that it will be judged. He complains of an inferior status vis-à-vis the specialist. Finally, he has not been trained on proper lines.

The Act is capable of adjusting the numbers of doctors to the amount of work that is to be done in a way that "private enterprise" never did. Platt sees no harm in basic salary combined with tapered capitation fee as a means to that end. In the health centres there is a remedy for professional isolation; a doctor will talk shop, with mutual advantage, to another doctor in the same health centre, where he would, for prestige' sake, have remained silent in the presence of a competitor, and he will know that at any time his case-records may have to be made available to his colleagues. These are powerful and unbureaucratic encouragements to maintaining a high standard of work.

The status difficulty has its roots in the bias of medical education. Platt holds it ridiculous that the practitioner of the future is trained wholly by the specialist. Surely he is right. Even if the content of this training were altogether appropriate, the respectful student could not help emerging from it with the impression that specialists are a superior order of beings. So they are, in some respects; but mostly they are not, in others. If the teaching staff included some competent general practitioners, broad in their outlook and wise in their experience of men, able to look the specialists in the face and prick their bubbles on occasion, the student's perspective would be truer, and the short-sighted stampede of the young into specialism would cease. To this end Platt offers the same suggestion as we did[2]—namely, that one or more health centres should be established as an integral part of every teaching school. The members of their staffs should be chosen for their ability to conduct general practice well, and for their capacity to teach the students who (singly for preference) would accompany them throughout their working day. We can think of no single innovation which could do more than this to raise the standard and realise the true function of general practice in the next generation.

BLOOD-FLOW IN BONE

THE failure of their many attempts at obtaining arteriograms of bone vessels in living subjects led Lamas and his colleagues[3] to investigate the intra-osseous circulation. They argued that a relatively slow bloodstream would be expected because none of the three physiological functions of the long bones—mechanical support of the body, storage of calcium salts, and hæmopoiesis—need a rapid circulation; hæmopoiesis and calcium storage are in fact facilitated by a slow bloodstream. Nor does movement of a bone, unlike that of muscle, require an extra supply of blood. When a dye was injected into the external iliac arteries of dogs they found that it took four seconds to reach a wound in the foot, seven seconds to reach the skin, and a whole minute to reach the bone-marrow (none reached compact bone). On the other hand, the dye was removed much more quickly from the marrow than the soft tissues; in less than three minutes it disappeared from the marrow, whereas it was visible for ten minutes in the skin. Studying the minute anatomy of the long bones they found that the nutrient artery describes many curves before entering the bone, and, after dividing into ascending and descending branches which run through the marrow, it ends in wide blood-spaces close to the epiphyses; these blood-spaces are in close contact with veins of wide calibre and very thin walls. This arrangement of blood-vessels reduces the pressure and speed of circulation in the arteries, and enables the veins to carry substances quickly away from the blood-spaces—hence the efficacy of therapeutic injections into the marrow. The slowness of the flow through the nutrient arteries is supported by the plethysmograph measurements of blood-flow in the normal humerus made by Edholm et al.[4] From their figures it is estimated that the amount of blood normally flowing through the whole skeleton probably does not exceed 100 c.cm. a minute, though it may be vastly more in Paget's disease.

Though all the long bones have a highly efficient venous drainage, the sternum is the bone of choice for transfusions and infusions because of its convenient situation, because it has excellent short venous connexions, through the internal mammary and innominate veins, with the superior vena cava, and because the compact part of the bone is very thin and easily pierced with the needle, the site of election being the upper part of the manubrium. The firm anchorage that the sternum gives for the needle was found useful in North Africa, where wounded were transported long distances with an intrasternal drip-transfusion running. It can also be made use of in the continuous administration of penicillin. Thus Giraud and Desmonts[5] injected 20,000 units of penicillin, in 250 c.cm. of serum, in two hours by this route, and two days later gave 40,000 units in 250 c.cm. of serum in five hours without encountering any difficulties.

ADSORPTION OF ENDOGENOUS TOXINS

FEW now believe that the various toxic chemicals, such as indole, skatole, tyramine, guanidine, putrescine, &c., formed by the decomposition of protein in the large bowel cause systemic disease or even the symptoms associated with constipation, though it has lately been suggested that their action may be partly responsible for the degenerative changes of old age. Most prefer to think that the barrier offered by the bowel wall and the detoxicating action of the liver together form an efficient protection against intoxication.[6] Nevertheless, since the substances are responsible for the unpleasant odour of fæces, their removal would be a great blessing to patients who are incontinent or have an artificial anus. Kaolin and activated charcoal have been much used for the purpose, but neither has provided the complete answer.

The ideal adsorbent should be completely effective in removing odour but should not interfere with intestinal synthesis of vitamins or with the absorption of foodstuffs and drugs. Martin and Wilkinson[7] tried to find a suitable adsorbent which will adsorb the toxic chemicals in the pH range of the gut. They found that 'Amberlite IR-4,' a synthetic resin, was very effective against indole and skatole, while all the amines tested (putrescine, cadaverine, tyramine, histamine, and guanidine)

During the whole treatment physical therapy must be in constant use. Patients need not be confined to bed for more than a few days after rib-resection, but at no time must observation or attention to detail be relaxed. Treatment must be active the whole time under the direct care of the surgeon.

THE NURSE AND THE SISTER

THE duties of the nurse, we are often reminded, have never been analysed: there is no clear answer to the question "what is a nurse?" If the principle of the two-year basic course in nursing, followed by a course for a senior qualification, is accepted it also becomes necessary to distinguish between the duties of the nurse and the duties of the sister. Some help in this is afforded by a recent analysis from America.

Dr. J. J. Golub,[1] director of the Hospital for Joint Diseases, New York City, plans to train what he calls "practical nurses" in a course lasting only a year, and to use such girls when trained to supplement registered nurses—the equivalent of our sisters—on the wards. The registered nurse, he says,

> "must continue to occupy the position of leadership in the profession. She may do bedside nursing. . . . She may be a hospital floor supervisor, or the head nurse of a nursing unit or a wing of a hospital, supervising the work of several other nurses; she may be director of a department of nursing or of a hospital's school of nursing; she may become a teacher of nursing; she may undertake special studies with the object of specialising in public health, anæsthesia, industrial nursing, medical social service, or hospital administration."

There are many nursing procedures, however, which need not be performed by a registered nurse, and he goes on to analyse 150 nursing practices which he assesses as suitable only for the registered nurse, or else as capable of being done by the practical nurse. All which fall under the heading of "control and supervision" are assigned to the registered nurse; they include supervision of all nursing services and ward staff, charting, preparation of patients for surgery, postoperative care and care of patients during recovery from anæsthesia, preparation of emergency trays, care of poison cupboard and medicines, supervision of linen and supplies, the serving of special diets, isolation technique, and reports on accidents and unusual occurrences. Under the heading of administration, however, only 2 out of 15 duties are assigned to the registered nurse: these are the writing of reports on staff shifts, and the task of reporting a patient's condition to the doctor. The practical nurse is given the jobs of receiving new patients, disposing of their clothes and valuables, looking after them at the time of discharge, preparing accounting reports on ward charges, answering telephone calls, taking messages, answering patients' signals, receiving visitors, delivering mail, arranging flowers, requisitioning supplies, drugs, and linen, and filling in routine slips for the examination of specimens. The practical nurse also undertakes the entire 24 duties listed under the headings of housekeeping and transport, which include regulation of heat and light for patients, supervising porters and ward maids, the lifting, turning, and carrying of patients, and the transfer of patients to the theatre and back. All the duties of assisting the physician—with dressings, transfusions, bladder irrigations, and other ward operations—fall to the registered nurse, the practical nurse only being required to furnish equipment and supplies.

The section of most interest is that headed "care of the patient": here, out of 64 procedures, 46 fall to the practical nurse and only 18 to the registered nurse. Those reserved for the registered nurse include preparation of fracture, traction, and cradle beds; nasal and rectal feeding; preparation of instrument trays; hot packs; cupping; the dressing of bedsores; eye, ear, and nose irrigations; the care of drips; and the giving of medicines and injections. The practical nurse, however, can undertake bathing and bedmaking, the serving of food, the feeding of infants and preparation of their food, the giving of bedpans and simple enemas, temperature-taking, poulticing, the care of the head, and routine treatment for scabies and the exanthems. Dr. Golub also suggests that the practical nurse could assist in other hospital departments, such as the nurseries for newborn infants, the special-diet kitchen, the occupational therapy department, and the theatre.

His analysis does not of course apply fully to British hospitals, because the nursing techniques differ a little. But in general the picture is the same; and it is enlightening to be told that of 150 common nursing practices 97, or 65%, do not need the attention of a highly qualified sister, but can be safely undertaken by girls with a much simpler practical training.

PSYCHO-ANALYSIS ILLUSTRATED

NOT only the general public but many doctors are curious to know what goes on in the psycho-analyst's consulting-room; for here is a branch of medicine which cannot be demonstrated to a class of eager students, or even to the solitary clinical assistant. Dr. Berg[1] has therefore done many of us a service by ringing up the curtain on those secret sessions and telling us exactly what one patient said and—which is more to the point—what he replied, or didn't reply. He does it cheerfully and competently, cleverly postponing his revelations, and presenting his tale with the skill of the natural storyteller. What the reader thinks about psycho-analysis at the end of it will no doubt depend on the bent of—or bends in—his own personality. In the case discussed, analysis was successful; and the situations revealed were of the kind which Freud has taught us to expect. Yet even Dr. Berg finds analysis puzzling at times. In theory, a man should benefit from an honest attempt at self-knowledge, from peeling off his layers as Peer Gynt peeled the onion; in practice, some do but some don't. Even if current interpretations of mental mechanisms are accepted fully, it is clear that an understanding of them will not, in itself, put the mind at ease. As Dr. Berg says, "insight alone is rarely sufficient to bring about more than very slight amelioration, and sometimes with the fullest insight amelioration of symptoms is the slightest." He attaches much importance to the emotional release which in this successful case accompanied the growth of insight; and the reader is tempted to wonder whether the emotional release without the insight might not be equally effective; or at least whether the same favourable result could somehow be achieved with less trouble and expense.

ROYAL SOCIETY

IN the list of 24 new Fellows of the Royal Society we are glad to see the names of several members of the medical profession and several others closely concerned in its work. Surgery is represented by Mr. Geoffrey Jefferson, F.R.C.S., professor of neurosurgery at Manchester, whose election will give much pleasure to his fellow clinicians. There are two biochemists (Prof. E. J. Conway, M.B., of Dublin, and Prof. H. A. Krebs, M.D., of Leeds), a member of the staff of the Imperial Cancer Research Fund (Dr. James Craigie), a physiologist (Dr. W. S. Feldberg, of Cambridge), and a geneticist (Prof. C. H. Waddington, SC.D., of Edinburgh). Among the three women now elected we are particularly happy to find Miss Muriel Robertson, D.SC., head of the department of protozoology at the Lister Institute.

THE Minister of Labour and National Service has nominated Mr. G. P. BARNETT, one of H.M. deputy chief inspectors of factories, to be chief inspector in succession to Mr. H. E. Chasteney, whose death was announced in our issue of March 8.

[1] Deep Analysis. By Charles Berg, M.D. Lond., D.P.M., physician to the British Hospital for Functional Mental and Nervous Disorders. London: Allen and Unwin. Pp. 261. 12s. 6d.

Boarding-out too has its dangers, as everyone knows; but in some cases it leads to happy adoption. Yet some voluntary societies (as Lady Allen of Hurtwood has pointed out[2]) discourage adoption, and one at least insists on a boarded-out child returning to the home at 16 for trade or occupational training, even though the foster-parents have come to regard him as their own child and wish to have a hand in settling his future. This is carrying responsibility almost into the realm of officiousness. Certainly adoption needs to be arranged with the greatest care, and foster-parents for boarded-out children must be chosen scrupulously; and certainly the sight of a houseful of sleek and happy children is more impressive to the casual visitor than a page of figures showing children successfully boarded-out. But the well-being of children is a subtle thing, not to be assessed easily from appearances. It would be unfortunate if this memorandum shook confidence in the Curtis Committee's findings.

GLOBIN OR PROTAMINE INSULIN?

GLOBIN insulin was originally introduced as a delayed-action insulin intermediate in time of action between soluble insulin and protamine zinc insulin. There was the further advantage that globin was cheaper and more readily obtainable than protamine. In spite of these claims it has not yet been widely adopted in Great Britain, though our American colleagues have been more enthusiastic. In a renewed attempt to clarify the issue, two American workers[3] have compared the action of these two insulins in 84 diabetics, several of whom were studied on more than one admission, thus giving a total of 97 hospital admissions. During the investigation the patients were kept in hospital and received a constant diet. Frequent blood-sugar estimations were made. When all the relevant data were assessed—blood-sugar curves, hypoglycæmia, and the patient's general state—it was found that, on the same doses, 65 were controlled better with globin, 25 with protamine zinc, and 7 equally well with the two insulins. Composite curves drawn from the average blood-sugar levels at different times of the day showed that the fasting blood-sugar was the same with the two insulins, but at every other time (i.e., 9 and 11 A.M., 1, 4, 7, and 11 P.M.) the blood-sugar was higher in patients receiving protamine-zinc insulin than in those receiving globin insulin. With globin insulin the blood-sugar returned to normal limits before lunch, supper, and midnight, which it never did with protamine zinc insulin. Glycosuria was significantly less with globin than with protamine zinc insulin; and, though the incidence of hypoglycæmic reactions was low with both insulins, only one mild reaction was recorded with globin, compared with three mild and two moderate reactions with protamine zinc.

It is often said that globin insulin is unsatisfactory because, if given in the morning, it does not control the blood-sugar during the following night. Roberts and Yater do not bear this out, for the fasting blood-sugar was the same in patients receiving the same number of units of globin and of protamine zinc insulin. In this country a combination of soluble insulin and protamine zinc insulin is often prescribed, on the principle that the rapidly acting soluble insulin will control the blood-sugar until the protamine zinc insulin comes into action. This combination often works in practice, but many patients find it more difficult to give themselves a single injection consisting of different volumes of two insulins than two separate injections of soluble insulin, morning and evening. Another disadvantage of protamine zinc insulin is that when given in the morning it may induce hypoglycæmia during the following night, when it may not be discovered until the patient has been in coma for several hours. With globin insulin this risk is minimised since hypoglycæmia is most likely to occur during the afternoon. There will always be diabetics who cannot be satisfactorily controlled with single daily injections of either globin or protamine zinc insulin. For these Roberts and Yater suggest two injections daily of globin insulin—one (70%) in the morning and the other (30%) about 3 P.M.

MANAGEMENT OF EMPYEMA

THE treatment of empyema has suffered from the failure to distinguish the various forms of pleural infection. This was clearly brought out in a discussion at the Royal Society of Medicine opened by Mr. R. C. Brock and Mr. T. Holmes Sellors on Feb. 5. It should be obvious that an acute and diffuse inflammation in the early stages requires different handling from a long-standing localised purulent collection, but since the introduction of chemotherapy there has been a tendency to concentrate on the sterilising effect and ignore the final healing processes.

The influenza pandemic of 1918 brought out very clearly the dangers of ordinary drainage in the early stages of empyema, and Graham's work showed that the patient already suffering from an acute pulmonary inflammation could ill support the addition of an open pneumothorax. The lessons then learnt resulted in delayed drainage being employed after preliminary and repeated aspiration had reduced the volume of the original pleural infection. An intercostal tube and closed drainage had a considerable vogue along with various methods of tidal irrigation and drainage, but the basic principles of treatment were not always fulfilled and results were often poor. Failure to remove the products of inflammation completely or to establish adequate and continued drainage were—and still are—responsible for chronic empyemata and consequent grave disability. The healing process or obliteration of the cavity has been greatly helped by physical treatment which by stimulating inspiratory efforts encourages lung expansion. Breathing exercises can play a very valuable part in chest work, but the most assiduous attention and concentration are required if they are to achieve their aim—the restoration of complete respiratory function.

The sulphonamides and penicillin have had a dramatic influence on the primary cause of empyema—pneumonia—but how far they have affected the incidence of empyema is still doubtful. In most cases penicillin will control the virulence of the pleural infection, and it is here that the drug is most valuable. The pleural fluid can often be sterilised by the injection of penicillin in suitable concentration after aspiration. Repeated aspiration and injection, persisted with along the lines suggested by Fatti and his co-workers,[1] can produce good results, but in the later and more localised forms of empyema the value of penicillin therapy is more doubtful, unless it is supplemented by orthodox drainage methods. Neither penicillin nor any other known drug will close an empyema cavity, though it may sterilise the contents. Established abscesses contain masses of debris and fibrin which cannot be removed through an aspirating needle or even an intercostal tube. Here it is more satisfactory in the long run to follow the standard principles of surgical drainage. In draining a localised pleural abscess the actual rib-resection should afford room not only for a wide-bore tube but for removing all fibrin masses and inspecting the interior—in short, for an efficient pleural toilet. The drainage-tube must be carefully sited to permit of gravity drainage and kept in position until the empyema cavity has been completely obliterated. During closure pleurograms enable the surgeon to visualise the shape and size of the cavity and make adjustments as required.

[2] *Times*, Oct. 21, 1946.

[3] Roberts, J. T., Yater, W. M. *Ann. intern. Med.* 1947, 26, 41.

[1] Fatti, L., Florey, M. E., Joules, H., Humphrey, J. H., Sakula, J. *Lancet*, 1946, i, 257, 295.

doctor and one dispenser to work on Sunday. The hour after lunch is most convenient because the dispenser can make up medicines brought in by other doctors having morning visits.

Apart from the ordinary surgery hours, each doctor would have one or more special sessions each week to which others at the centre may refer cases. Each case would be seen by appointment, the appointment book being left open for any of the doctors to make an entry.

The dental surgeon would have his own department, but would share the waiting-room and minor surgical department (for extractions), and share the staff, one member giving her whole time to him.

The physiotherapist would have his own department and share waiting-room and staff. Dispensers would be organised so that two were on duty from 9 A.M. to 7 or 8 P.M., meal-times being staggered so that one was always on duty. Receptionists and nurses would have staggered hours too, so that one at least was on duty each day for the six weekdays. Secretaries and cleaners would work the hours usual for offices.

Arrangements must be made for a rota of duty hours for doctors for emergency calls out of hours. As an anæsthetic is occasionally required, or the doctor on duty is busy with a case when another urgent call comes, two doctors should be on duty at a time, the second acting as deputy or assistant to the first. Illness, epidemic, and holidays must be covered by drawing on the locum pool. If doctors are to be adequately employed it is quite unfair to expect them to do another's work.

Communication with the doctor on duty should be by telephone, with facilities granted by the Post Office telephones. The doctor's telephone should be that of the health centre only. Calls out of hours should be taken by the Post Office and connected to the doctor on duty. The Post Office would be supplied with the lists from each centre. This arrangement is used in America and could easily be adopted here.

Monthly meetings of the doctors, at which the senior would preside, would undertake the ordinary business of the centre. Other workers at the centre would be able to bring any business which concerns them.

THE CENTRE

Two waiting-rooms will be needed (*a*) for ordinary surgery hours, and (*b*) for special consultations, dentist and physiotherapist. Each will require lavatories. During children's sessions one room should be used for children and one for adults.

The waiting-rooms should be large and airy. Patients don't look at pictures and hardly ever read notices. They abhor the wireless. There should be plenty of chairs and a small table with pen, ink, and blotter. The name of the two doctors at surgery should be on their respective doors of waiting-room (*a*). The patient should show his card to the receptionist and receive a numbered disk in return so that his turn is assured. The disks for the two doctors should be coloured differently, the colour being indicated under his name on the door. The receptionist takes out the record card of each patient and carries a batch to the doctor when signalled to do so.

In waiting-room (*b*) the other receptionist—or secretary or dispenser when only one is on duty—admits the patient, takes the name, confirms the appointment, finds the record card, and in due course notifies the doctor or dentist concerned. The patient is then shown into the appropriate room. There should be a telephone in each room for intercommunication.

Four consulting-rooms will be needed—two opening on to waiting-room (*a*) and two convenient for waiting-room (*b*). An examination-room should be placed between each pair of consulting-rooms, with access to both. There should be an X-ray and physiotherapy room, three rooms for the dental surgeon, one minor-surgery theatre, one rest-room with two beds, one pathological laboratory, and a large office.

The staff and the doctors would each have a room, with lavatory attached. A caretaker's flat should be incorporated, while outside should be a car-park and an under-cover bicycle park.

Health centres should be no farther than two miles apart in the large towns and should be placed where there are good transport facilities.

A PLANNED PSYCHIATRIC SERVICE

"PSYCHIATRY is the personal aspect of medicine." The regional medical advisory committee of the Nuffield Provincial Hospitals Trust have lately received a report from their subcommittee on psychological medicine in which this personal aspect is considered in its three manifestations—somatic, psychological, and social. Regional planning of psychiatry, the subcommittee suggest, can be considered under the heads of day-to-day practice, preventive psychiatry, and treatment.

In day-to-day practice there are five main types of case, needing different types of building and equipment. The serious mental disorders need mental hospitals; the neuroses need outpatient clinics, neurosis centres, psychiatric units, and wards or beds in general hospitals; defectives need colonies; difficult or delinquent children need children's departments staffed with social workers and educational psychologists as well as psychiatrists; and, finally, cases of psychopathic personality—habitual offenders, drunkards, and other social misfits—may need all these services for themselves or their children, as well as the help of well-trained social workers to maintain links between the psychiatric service and other social organisations.

These services can be dispensed mainly from three types of centre—the mental hospital, the associated psychiatric department in a neighbouring general hospital (offering both inpatient and outpatient care to adults and children), and the neurosis centre. The report, taking the incidence of serious mental disorder as 3·9 per 1000, and the optimum size of a mental hospital as 1000, suggests that 250,000 is a convenient body of population to be dealt with by such a triad. In the Berks, Bucks, and Oxford region there are three triads of the kind, at Oxford, Reading, and Aylesbury. Some 1100 new mental-hospital beds, it is estimated, are needed, and the subcommittee suggest that these should be provided in a new mental hospital in the Windsor-Slough-Maidenhead area; this, in conjunction with established general hospitals and a small new neurosis centre, would provide a new triad for this heavily populated area. The existing triads would also need completing in some respects: Oxford and Reading need psychiatric units in general hospitals, and Reading still lacks a neurosis centre. Proposals for a colony for neurotics have been studied with sympathy, but the subcommittee do not at this stage recommend that such a colony should be set up. For mental defectives, however, they feel a new colony, admitting some 2000, should meet the needs of the region.

The difficulties of providing psychiatric treatment for children are more complex. They suggest that a child-guidance centre, mainly educational, under a psychologist, and controlled by the education authority, can act as a filter for children who, though referred for poor school work, are in fact psychiatrically ill; these could be sent on to a child psychiatric clinic under the health authority. Psychiatrists from the clinic should attend as consultants but not as administrative officers at the child-guidance centre, and educational psychologists could be exchanged on the same terms with the psychiatric clinic. Each would thus have a share in the work of the others, and maintain close personal touch. The

A GROUP PRACTICE

S. C. ALCOCK
M.B. Edin.
PRESIDENT, BERKS PUBLIC MEDICAL SERVICE

THE new health service will mean vast changes in the administration of medicine, but the doctor's work will remain precisely the same. After some years' experience there may be alterations in the nature of the work performed by individual doctors, but at the moment we are only concerned with the commencement of the scheme.

Doctors can be divided into three classes: (1) specialists, (2) general practitioners, and (3) whole-timers. Under the new scheme the whole-timers will continue to do the same work in the same places as at present and the specialist will be based on a hospital. It will be left to the general practitioner to staff the new health centres, and these places will in fact become the new doctors' surgeries. The main change in the new scheme therefore will be to separate the doctor's residence and his place of work.

General practice has altered in the last 25 years so as to provide a group-practice service which has largely replaced the single-handed practitioner. In some smaller towns the group or partnership comprises all the practitioners in the town. This change in the manner of general practice has led to another important change. With the widening field of medicine a stage has been reached when it is beyond one man to cover the whole field. The larger partnerships have thus become partnerships of minor specialists as well as general practitioners; indeed the general practitioner coming into a large partnership often starts his life with extra qualifications or diplomas, or special experience in one of the branches of medicine.

This general trend will determine the type of work and the nature of the staff of the new health centre.

ADDITIONS TO THE ORDINARY G.P. WORK

It is to be hoped that a national service will bring closer together the three main sections of the profession—the consultant, the G.P., and the M.O.H. This being so, the scope of the G.P. will be widened. The obstetricians who are to attend labours will be able to do their own antenatal examinations, while child welfare will be passed to the pædiatrician. Those surgically inclined will require a theatre for minor operations and a rest-room. Doubtful fractures and malpositions of the fœtus should be confirmed by radiography on the spot, without in any way attempting to replace the function of the specialist radiologist. Facilities for simple blood chemistry and microscopy must be provided too. There will be a place for the dental surgeon and the physiotherapist at the health centre. The dental surgeon will need to share the operating-theatre and the radiographic facilities, besides having his own department.

SIZE AND TYPE OF UNIT

The size of the unit will depend solely on the number of G.P.'s employed there. There will be no provision for outside specialists, because there will not be enough of them to visit all health centres, nor the apparatus they require for their detailed investigations.

In the less populous areas the size of the unit will vary from one doctor upwards to the ideal number of about six. In the compact areas of the great cities this number may conveniently be exceeded considerably, but I believe six to be the best number to start with in the towns and usually in the cities. Where fewer than six doctors are working, there would have to be a corresponding reduction in staff and accommodation, but the centre here described should be regarded as a model to approximated as nearly as facilities permit.

Minor differences in the type of centre will occur in the great cities. I cannot imagine that the same type building or furnishings will succeed equally in Mayfair and Whitechapel. The day is rapidly approaching when they will, but it is not here yet, and planners must keep in mind that the primary object of a health centre is to get people to go to it.

PERSONNEL

Where six doctors are to work together, and where the medical interest of each differs to some extent, it is impossible to imagine that they can work as individual practitioners. The health centre must therefore be a large partnership where patients are accepted by the centre and not by the individual doctor. This would not in any way preclude a patient attending the doctor of his choice whenever that doctor is available. For the organisation to succeed there must be a chief doctor who will assume responsibility for the working of the entire unit and everyone in it. Even with the other doctors there should be some system of gradation of seniority, especially in respect of the mature doctor and the newcomer straight from hospital. These considerations would entail differences in remuneration.

Though the special interests of the doctors need not be similar in each health centre, I suggest a suitable arrangement would be:

1 surgeon.
1 physician.
1 gynæcologist-obstetrician.
1 pædiatrician.
1 anæsthetist.
1 oculist.

One or two of them will undertake the minor radiology or minor pathology.

It must be remembered that all these doctors are essentially G.P.'s. The surgeon would not undertake major surgery; the gynæcologist-obstetrician would not do his own cæsareans; nor would the oculist do much more than refraction work. I believe, however, that all these doctors should have an opportunity to work as registrars or clinical assistants at the hospitals. Dispensing would be undertaken at the centre and thus the personnel can be determined as:

6 doctors.
1 physiotherapist.
1 dental surgeon.
3 dispensers }
2 receptionists } one to act as manager.
2 secretaries }
2 nurses }
Cleaners and caretaker.

ORGANISATION OF THE WORK

The main purpose of the health centre is to provide a place where patients are able to see their G.P. This means the arrangement of consulting hours. After 25 years I have found that 2 consulting hours a day for 3 days a week is convenient for patients and gives the doctor ample time to see special cases—i.e., those referred by other members of the centre—and to visit his patients too. With six doctors working in pairs, consulting hours would be thrice daily as follows:

	Morning	*Afternoon*	*Evening*
Monday	A.C.	A.E.	C.E.
Tuesday	B.D.	B.F.	D.F.
Wednesday ..	A.C.	A.E.	C.E.
Thursday	B.D.	B.F.	D.F.
Friday	A.C.	A.E.	C.E.
Saturday	B.D.	B.F.	D.F.

The obstetrician and pædiatrician should have afternoon sessions, since these are most convenient for women and children and most inconvenient for workers. Arrangements for the others must fit in with their other commitments—e.g., at hospital. There must be a rota for one latest statistics. Nor do I recall any evidence of, or reference to, a higher incidence among females over 15 years of age in any way comparable with the figures quoted above.

It may be that, among the strains of *C. diphtheriæ* now prevalent in Germany, there are some towards which the population has had little chance of gaining immunity and to which adults are as susceptible as children. The protection conferred by artificial immunisation gives a relative immunity to younger members of the community, so leading to the abnormal age-distribution. It may not be altogether far-fetched to postulate a higher degree of female susceptibility, as there are undoubtedly diseases, not all of them infectious, where a differential incidence between the sexes is well marked.

Unfortunately the present difficult circumstances preclude the typing of *C. diphtheriæ*. The director of the local bacteriological laboratory, Dr. K. Schlirf, of the Landes Hygiene Institute, is familiar with the work of MacLeod and his colleagues but, through lack of time and materials, cannot carry out the necessary investigations. He believes the common strain to be *gravis*, but his opinion cannot be based upon up-to-date work.

If the foregoing suggestions are true, a similar situation in respect of age- and sex-distribution is likely to develop in England. This raises the question how often artificial immunisation should be repeated to maintain reasonable protection of the population at all ages.

SUMMARY

Notified cases of diphtheria in Land Oldenburg during the autumn and winter 1945–46, grouped according to age and sex, showed a higher incidence over than under 15 years of age and among women than men.

These findings were not due to abnormal external conditions but had been observed for some years in Germany.

The question is discussed whether this is due to artificial immunisation of children, increasing the number of carriers and so affecting a rather susceptible adult population, or to the presence of a strain of *C. diphtheriæ* readily attacking all age-groups, against which artificial immunisation had protected the younger members of the community.

The possibility of special susceptibility of females is also discussed.

Similar findings may be reported later in the United Kingdom.

INFECTIOUS DISEASE IN ENGLAND AND WALES

WEEK ENDED MARCH 15

Notifications.—Smallpox, 2; scarlet fever, 1336; whooping-cough, 2407; diphtheria, 184; paratyphoid, 5; typhoid, 6; measles (excluding rubella), 11,269; pneumonia (primary or influenzal), 1076; cerebrospinal fever, 107; poliomyelitis, 5; polioencephalitis, 0; encephalitis lethargica, 1; dysentery, 73; puerperal pyrexia, 148; ophthalmia neonatorum, 78. No case of cholera, plague, or typhus was notified during the week.

Smallpox.—Of the 2 cases of smallpox, 1 was notified at Grimsby, and the other in London.

Deaths.—In 126 great towns there were no deaths from enteric fever. 2 (0) from scarlet fever, 3 (1) from diphtheria, 19 (0) from measles, 22 (1) from whooping-cough, 97 (9) from diarrhœa and enteritis under two years, and 80 (10) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 317 (corresponding to a rate of 30 per thousand total births), including 40 in London.

Smallpox

Up to March 24 1 further case was notified. This was in a man under observation as a ward contact with the earlier London case. The patient was revaccinated on March 9. On March 20 a sparse eruption developed. On March 21 he was transferred to the Surrey County Isolation Hospital.

In England Now

A Running Commentary by Peripatetic Correspondents

WITH the recent ministerial pronouncement that a thatched roof has as many virtues as one of slate or tile, no-one will be surprised if we are asked to forgo damp-proof courses to save impervious materials, have mud floors to ease the timber scarcity, and make candles the normal source of lighting to reduce the call on electric fitments and power. Indeed, we may be persuaded to return to the old conservancy system of the privy or the family pail, particularly so if the Ministry of Agriculture joins forces with the Ministry of Health in a combined operation to enliven the compost heaps of England. Here, by one enactment, would be brought about a greater garden fertility and an increased vegetable production, so leaving our cramped shipping space for the importation of peaches, grapes, and nectarines, which seem to have replaced potatoes, turnips, and carrots in the greengrocery shops of this topsy-turvy world.

* * *

The elderly farm-worker shook his red-tasselled night-cap at the predicted thaw. I took his cue and prepared a lengthy visiting-list for the morrow. The day came cold and dull, and over a chilly picnic lunch snow was seen falling on the hills. By the time the weekly country surgery for the upland villagers was over the snow was driving and drifting. Within a mile I had to call six P.O.W.'s to clear an ever-increasing drift. Seven miles home, but a fifteen-mile round still to be done. The blizzard was now a fine horizontal hail which stung the face between car and farmstead. As darkness fell the headlamps showed only a fast-moving wall of snow, which called for halts to find the roadway.

Wednesday revealed a heavy fall steadily increasing. An early message to the only garage with a jeep quickly brought the proprietor and the chariot to the door with his assurance that he was glad to help a medical man. A parturient mother five miles away proved that the night's fall had blocked all four possible roads, and after two hours spent exploring either bank of the river I did the ten miles in four hours with spades and willing helpers. in spite of blizzard conditions. An evening hospital call—a strangulated hernia—coincided with the last of the snowfall.

A market-day round of the town on foot next morning proved that all transport was at a standstill. But a call from a man with a shoulder injury brought the jeep out again and four miles of drifts were negotiated to the rendezvous—a crossroad inn—where eight weary bread-carriers who had somehow been stowed behind were disgorged. The return was uneventful, though my sitting casualty looked rather white, and he revived on hot sweet tea from the halfway village store.

A sunny Friday called for a journey with the midwife to a hypertensive *multigravida*. Five miles through a snowbound countryside beside the half-frozen river teeming with duck, with the sun frigidly outlining the distant Welsh hills; then a mile and a half plodding over the deeply covered field-paths. After deliberation the mother agreed to the proposed journey, which no ambulance could attempt. A slow undulating tramp for an 11-gravida who had not passed her doorway since the January fall of snow.

The week closed with a call from an unknown Northern tertigravida, who was at term, with a bad history. No nurse could reach her. The forest lane to her new home had been snowbound for six weeks. A visit to the road-surveyor brought the promise of a bulldozer. By tea-time the three-mile up-hill job was done and my jeep reached the door. As I write she is in labour, having been collected by more orthodox means down the snow-cleared lanes.

This brilliant Sunday morning brought some thaw, and a failing heart was reached after three miles of highway and five of gated field, stockyards, and orchards. In the 100-acre field the jeep was in her element. Reconnaissance was good—my gardener was born in the parish.

This afternoon a post mortem for the coroner, on a body brought seven miles by bearers and twelve by military lorry (a climatic casualty), was interrupted by three calls from an April-due primigravida—a journey of eight miles, four by tractor-marked surfaces followed by subcommittee advise against psychiatric organisations exclusively for children, because they lead to specialism within a specialty and perhaps to loss of a balanced view of children's disorders and difficulties.

They wish to see departments of preventive psychiatry set up, analogous to the present local-authority departments of health—that is, primarily administrative, statistical, and social, but not clinical. They touch on the possible appointment of a medical officer of mental health, but without enthusiasm. If appointed, they say, he should not hold a position of authority in hospital administration. Psychiatry should be taught, they consider, in a psychiatric teaching unit in the university, on the same footing as internal and social medicine. The unit should be concerned mainly with postgraduate teaching and research, but should also teach undergraduates in the hospitals which provide the psychiatric service.

The subcommittee rightly insist that there must be no watertight compartments: though the units in the service should be largely autonomous, their policy and the broad general lines of their form should be discussed and decided at the regional level. A single group of doctors should serve the component hospitals of each triad, and should interchange work with each other and with the doctors of the mental-deficiency colony. Their common meeting-ground would be the psychiatric department of the general hospital. The plan is essentially simple, but it provides for that close nexus between the component parts of a regional psychiatric service which so far has been lacking—and not only in Berks, Bucks, and Oxon.

Public Health

AGE AND SEX DISTRIBUTION OF DIPHTHERIA

IN OLDENBURG, GERMANY

J. V. WALKER
M.D. Birm., M.R.C.P., D.P.H.
LIEUT.-COLONEL R.A.M.C.

BETWEEN Oct. 1, 1945, and Feb. 28, 1946, 3538 cases of diphtheria were notified in Land Oldenburg, an area somewhat larger than Lincolnshire, with a population of about 750,000, and for the most part flat and low-lying, mainly given over to agriculture and dairy farming, with two cities of about 100,000 inhabitants, one of them severely damaged by war operations. It may be taken as a typical region of the North German plain, and the age- and sex-distribution of diphtheria described below are shared by the adjacent area administered from Aurich.

The distribution according to age and sex was as follows:

Age (yr.)	*0–5*	*6–15*	*16–25*	*26–35*	*36–45*	*46–65*	*Over 65*
Males	392	276	319	121	71	52	11
Females	353	363	881	376	171	143	9
Total	745	639	1200	497	242	195	20

Of the total number of notified cases, 2154 (60·9%) were 15 years of age and over, as compared with 30·9% in 1945 in U.K.[1] At all ages over 5 years until the latest age-group, females were more numerous than males, giving the following percentages:

Age (yr.)	*0–5*	*6–15*	*16–25*	*26–35*	*36–45*	*46–65*	*Over 65*
Percentages	47·4	56·8	73·4	75·7	70·7	73·3	45·0

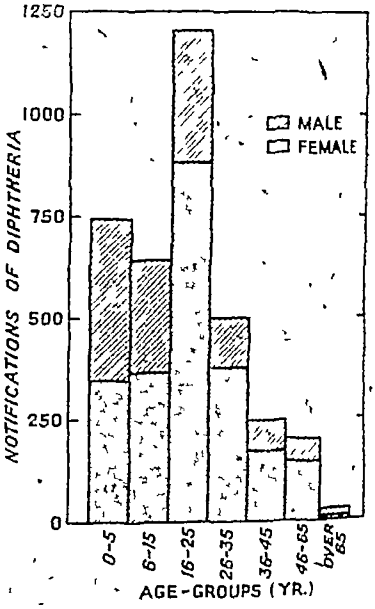
The relative distribution according to age and sex may be better appreciated from the accompanying figure.

The fatality-rate presented no unusual features; was higher for the most part than in U.K. in 1945[1]:

Age (yr.)	*0–5*	*6–15*	*16–25*	*26–35*	*36–45*	*46–65*	*Over 65*
Fatality-rate in Oldenburg	14·2	2·3	2·1	2·2	4·6	5·6	35·0
Fatality-rate in U.K., 1945	7·7	3·5	1·4	3·8			

The fatality-rate showed no significant features between the two sexes (6·4 males, 4·6 females).

During the period concerned diphtheria was common and was evenly distributed throughout the Land, at no place reaching epidemic proportions. The weekly notification-rate reached a maximum of 28·5 per 100,000 of population for the week ended Nov. 10 and again rose to 27·3 per 100,000 for the week ended Jan. 5. Between these periods it averaged about 20 per 100,000, and since January the rate has steadily fallen.



Age- and sex-distribution of diphtheria cases in Land Oldenburg.

Though living conditions in north-west Germany were, throughout the period under discussion, highly abnormal, there is no evidence that the epidemiology of diphtheria was particularly influenced by any factor, and the age- and sex-distribution described above have been, according to the medical officers of health of the area, observed during the last few years. Until the later thirties diphtheria was uncommon in Oldenburg and did not until its recent recrudescence show its present features. Hitherto it had been much more frequent among children under the age of 15 years than among adults.

DISCUSSION

Two matters of epidemiological interest arise: the high incidence of diphtheria among adults relative to children, and the preponderance of female cases. The German medical officers of health explain both by reference to artificial immunisation of children. This has been introduced in recent years and is fairly widespread, 60% of children under the age of 15 years in Land Oldenburg having been immunised. It is argued that this has led to a higher incidence of virulent carriers among insusceptible children, with consequent greater risk to non-immune adults. Since during the earlier part of the century the disease was uncommon, immunising subinfection was uncommon also, and so the adult population is less naturally immune than in U.K. Moreover, since women have more to do with children than have men, the differential sex-incidence is explicable by the same cause.

Whether this can be accepted as a wholly satisfactory explanation is open to question. In some parts of the Land the proportion of immunised children is as low as 25%, but the age- and sex-distribution is the same everywhere. In England artificial immunisation has been practised since the early thirties and intensively since 1940, but no similar age-distribution is apparent in the

---

1. *Lancet*, 1946, i, 754.

4. The significance of nursing and the importance of the nurse's part as a citizen and as a key person in the National Health Service and in her own hospital should be stressed, so that the nurse in training has a sense of pioneering, of adventure, and of social importance.

5. A diversity of post-certificate courses up to university level should be planned to succeed the basic course, and these would precede promotion and specialisation.

As to anatomy, physiology, and psychology, these terms should disappear from the basic course (if only because they lose their meaning unaccompanied by the experimental studies which nurses cannot undertake). In their place the structure and function of the living body and mind should be studied, and should be taught in non-technical language by experts (not necessarily doctors or nurses, unless they are in fact experts) willing to give the very large amount of time and energy necessary for this type of teaching. The best illustration I know is Sir Arthur Keith's *Engines of the Human Body*, lectures given to a juvenile audience at the Royal Society; and what a lot of trouble he must have taken over them!

The application of this knowledge should be at the bedside. It should include recognition of surface markings necessary for treatment: e.g., location of orifices; recognition of failure of function due to structural defect and damage (the mouth no longer self-cleansing, the skin unable to maintain its resistance against pressure, the heart no longer an efficient pump, the blood depleted of its oxygen); recognition of behaviour influenced by fear, suspicion, and pain (the patient operated upon for cataract suddenly plunged into outer darkness).

All these are matters for an expert educational body, which could draw upon the special knowledge possessed by members of the General Nursing Council. Most nurses would probably agree that the time has come to link up the education of nurses with the general educational system of the country.

G. B. CARTER.

SIR,—You put forth a proposition which opens up an important question:

> "Education, alike for medicine and for nursing, should, we suggest, be directed towards the good of the sick—not towards advancing the status of nurse or doctor."

But the status of the nurse is in fact in danger at present. The tendency is to regard her from the industrial standpoint and to concentrate attention on such matters as hours, wages, and what is virtually output, as though she were a producer; and to limit her education at the same time to just what is necessary to carry out bedside nursing.

But a nurse is not a producer; she belongs in a very good sense to the class of the guardians of the people. Accordingly she herself and all connected with her welfare should resist the attempt to lower her status to that of the artisan. On this view the broadest life, the widest outlook, and the best education should be hers; nothing ut good should flow into eye and ear; and the aim f her teachers should be to produce first a good nurse nd next a good woman.

If the difficulty in recruiting nurses were approached rom the standpoint, "What can I put into her?" nstead of "What can I get out of her?" then the ifficulty would most likely dwindle and disappear. f the worst thing in the past were to treat her as a nun, he worst thing at present is to look upon her as an rtisan.

The complaint cited in your page, sir, that the nurse of today is not being trained primarily to care for the sick, comes, one notes, from an American source. To the best of my knowledge and belief there is no deterioration in the nurse's care of the sick in this country. It might be maintained that if nursing were raised to the highest status there would still not be enough nurses. In that case two classes of nurse would be necessary, one with the equivalent of an honours and one with a pass degree: but one hopes that this would not occur.

TYPHOID-PARATYPHOID (VI) VACCINE

SIR,—It was interesting to read in the *Bulletin of Hygiene* last September (p. 615) the résumé of an article by Ruiz Merino[1] on a new typhoid-paratyphoid vaccine with brilliant green, for which better results are claimed both in animals and in humans than with alcoholised, phenolised, or other types of vaccine. If this and other advantages are confirmed the vaccine will undoubtedly be a great help in the fight against enteric fever, particularly in the tropics.

Some time ago, in an attempt to find out if an effective typhoid vaccine with potent Vi antigen could be produced without alcohol, which was very expensive at that time, I tried several chemical and physical methods to kill the organism without affecting the Vi antigen. The simplest and most effective method found (brilliant green was not tried) was to sterilise the bacterial suspension with merthiolate, which was subsequently used in weaker concentration to maintain sterility—the principle used by Felix in his alcoholised vaccine. The effective concentration for killing the bacterium was found to be 1 in 10,000, and the preservative strength 1 in 20,000 to 1 in 30,000. Rainsford tried higher concentrations and discarded the vaccine as unsuitable.

The vaccine was stored in the cold, and at intervals of about a fortnight it was agglutinated against pure Vi-agglutinating sera and was found to keep its Vi-agglutinability undiminished up to 4 months, with only a slight drop during the next 3 months. It compared very favourably with alcoholised vaccine prepared by Felix's method and stored under identical conditions. Its protective and agglutinogenic properties have, however, not yet been fully determined. A small number of people were inoculated with it, and its Vi-agglutinin response appeared to compare favourably with that following the injection of alcoholised vaccine.

No claim can yet be made that this vaccine is superior to others, except on the grounds that it is simple to prepare and reactions to injection are few, and only mild and transient.

Under post-war conditions it is not now possible to carry out any extensive investigation with this vaccine here, and we hope that workers more favourably situated may be interested in it.

Department of Bacteriology, College of Medicine, Singapore. N. K. SEN.

TREATMENT OF TUBERCULOSIS

SIR,—Your correspondent, Dr. J. V. Hurford (Feb. 15), is concerned lest undue emphasis be put upon my statement respecting the recovery of many patients from tuberculosis, who before radiography had been unaware of its presence and had not received any institutional treatment. He suggests that I base my opinion on the radiographic evidence of primary tuberculous infection rather than on post-primary progressive tuberculosis.

From a serial radiography of patients with tuberculosis I have learnt that we cannot assess the gravity of past disease from the present radiographic appearances. Though we can be amazed at the spectacular spread of the progressive disease, we can be perhaps even more amazed at the disappearance, or almost complete disappearance, of spectacular radiographic "lesions." We can see "minimal" calcified foci in the lungs of most patients who are suffering from acute bone tuberculosis. We have seen patients with such "healed" lesions develop progressive and even fatal tuberculosis. For these reasons I opposed the opinion of the advocates of mass radiography that such lesions should be ignored as if they indicated established immunity: they should call for advice and added care against any influence which might lower the resistance.

I fully support the views on the "old-fashioned" sanatoria so ably expressed by Dr. J. H. Crawford (Feb. 8) and Dr. Temple Clive (Jan. 25). The claim put forward, that with increased surgical and other interference the five-year survival-rate has increased, has little to support it. The number of deaths from pulmonary tuberculosis has been progressively declining with improvement in social conditions; it fell from 53,858 in 1910 to 27,176 in 1928—i.e., before these "heroic" measures were adopted. With the increased

four of virgin snow. A fully dilated os, with no midwife, and the patient staying with friends, proves necessity the mother of invention.

So I turn another page of my B.-W. diary only to carry forward the unvisited mother of the mid-week. A message that the infant has a cold brings a fresh problem. The four roads are still closed, but the railway has been cleared, so I propose the midday train. By telephone a farmer has promised a tractor at the siding and the railway company a goods engine if I miss the return train. As I doze in the warm corner seat I wonder what the red-tasselled head will think of a visit by jeep tomorrow.

* * *

In thinking of the details of a national health service one sees that what is lacking is a comprehensive body of agreement as to what we want—in short, a philosophy. Without this we are but tinkering at various and differing parts of a system, dealing with a loose brick here, adding a cornice there, like a pack of jobbing builders. Our aim, as I see it, is to make it safe to live; but ultimately happiness and peace in living is more important than mere physical integrity. In our efforts to produce a healthy body do we think enough of the man within it? If he will, he can make hay of all our planning. Perhaps we had better take counsel with him.

* * *

From earliest Childhood, Albert South
Was given to Placing in his Mouth
Whatever Objects, square or round,
He saw reposing on the Ground.
His mother wept, his father said,
(Sending him, in Disgrace, to Bed),
" Don't pick up candy from the floor—
You don't know *where* it's been before."
His kind relations, each in turn
Bawled in his ear and beat his stern
But made no progress, even so,
Against his Oral Libido.
I cannot tell that Albert paid
The slightest heed to what they said;
He scavenged still, grew rude and wild,
More like a Pig Bin than a Child,
Turning from wholesome Bread and Butter
To Toffee Apples from the Gutter;
Until at last he chanced to meet
A Box of Tablets in the street.

* * *

The pills went down, the pulse went up:
He did not come to dine or sup—
And when his Relatives arose
They found him lying Comatose.
The great Consultants held out hopes
And squinted down Ophthalmoscopes,
Owning that Albert had them beaten
Unless 'twas something that he'd eaten—
Until that night, before the News,
They heard a Notice from the screws
That Mrs. B, the fast old witch,
Had dropped some pills in Putney, which,
Consumed unbid by medicos,
Might dorsiflex the taker's toes,
And persons having Information
Should Telephone the Nearest Station.
The Great Consultants all looked grim,
And each in turn remarked " That's him!"
And tried to resurrect young Bert
With Picrotoxin, and a Squirt.

If my Stipendium were Enough.)

Letters to the Editor

THE STUDENT NURSE

SIR,—The General Nursing Council's efforts to [illegible] what is " proper training " are hampered because [illegible] authorities have never decided what is the work of a nurse and how many nurses are required to do it. This is not to whitewash the G.N.C., for they should long have realised the difficulty and acquired the ne[illegible] powers to deal with it, or as you put it matched power with responsibility. In consequence we are faced with muddled situation whose dominating feature is that " student " nurses must undertake to perform the routine work of the hospital in return for teaching which may be quite inadequate and has never been properly planned on sound modern educational lines. The result is that a high proportion leave (up to 60% in many hospitals), and it looks as if we shall never know what a paradise for patients (and staff) a hospital run with fully trained personnel might be.

These methods date from 1860. All we have done since is to call the probationer a student nurse and pile upon her a more and more detailed study of anatomy and physiology and other things, without any reconsideration of what she wants it for or whether she wants it at all. On the one hand we have the dismal pronouncements of those who want nurses to be devoted and dutiful (and dull), and would cut out from their training everything thrilling in modern medical science—at a time when it is more exciting than at any time in its history. On the other hand we have the nurse educationists, who, feeling the limitations of their own anatomical education, would load the nurse with every facet of the vertebræ and the functions of the obscure thymus in the vain hope that thereby professional status will be advanced.

It is obviously impossible to change the present state of affairs overnight, but the time has surely come when the question of a curriculum and training programme for nurses belongs to national educational policy. It has become too large a matter for the General Nursing Council. I suggest that the Interdepartmental Committee (whose report is eagerly awaited), now sitting under the chairmanship of Sir Robert Wood, of the Ministry of Education, should form the nucleus of a commission entrusted with the task of preparing a training programme and curriculum for nurses. In this connexion the report on practical nursing of a working committee appointed by the United States Office of Education[1] and recently published is well worth study. Such a commission would have to take into account the fact that if patients are to get the attention they need there is room within the nursing profession for women of both simple and advanced educational attainments. Also that the hospital community, like a hotel or a household, requires much personal and domestic service which should be skilled but is not specifically nursing. These and many other considerations, still imperfectly understood, would influence the content of the curriculum and the manner of training.

In my judgment the curriculum and training programme, whatever the type of candidate, should have *the following features*:—

1. It should be intrinsically interesting and satisfying, even exciting to those who study it; therefore it must be flexible.

2. It should be possible, especially in the basic course, to make a distinction between teaching given to excite interest and stimulate further observation and study in those capable of it, and fundamental facts and skills on which the safety of the patient and the efficiency of his treatment depend.

3. Only the fundamental facts and skills should be the subject of compulsory examinations; these should be devised in the simplest possible manner but should demand high marking for pass.

[1] Practical Nursing. An Analysis of the [illegible]
with Suggest[illegible]
(Misc. No. 8)
Division, Offi[illegible]
Government [illegible]

But the usual protein hydrolysates intended for therapeutic purposes are prepared from proteins of high biological value, such as casein, lactalbumin, and meat, by enzymic digestion with which there is no destruction of any essential amino-acid. If an acid hydrolysate is used (mostly for parenteral use) it is fortified with tryptophane and cystine to make up for that lost during hydrolysis.

In the light of these facts the remarks of the Gillmans about protein hydrolysates in general are hardly justifiable. It is likely that in infantile pellagra the primary requisite is something contained in 'Ventriculin,' in the absence of which the administration of large amounts of protein or protein hydrolysates may further tax the already damaged liver. It would have been interesting to try ventriculin together with a good pancreatic digest of casein or papaic digest of meat.

OF NOT SMOKING

SIR,—Your annotation of March 15 ran: "It is not easy to gauge the priority which tobacco may justifiably be given. . . . Unfortunately, there is no yardstick for the measurement of tobacco's virtues." You clearly did not consider it necessary to indicate what are tobacco's virtues.

In my view, based on 12 years as a cigarette-inhaler followed by 20 as a non-smoker, there is no virtue in tobacco-smoking, just as there is none in opium-smoking. Addicts of drugs, including tobacco, delude themselves that their drug possesses unique psychological virtues—e.g., the sustaining of morale. What the drug really does is to appease temporarily their craving; and craving for a drug is a psychopathic urge generated as a late action of certain drugs. As it is appeased, so also is it generated.

The facts that tobacco is a toxic and comparatively powerful drug of addiction [1] and that it is therapeutically useless warrant the conclusion that there is no justification for any expenditure on it whatsoever; also that it is our duty, as keepers of the nation's health, to abolish tobacco-smoking, on health as well as on economic grounds.

Wallasey. LENNOX M. JOHNSTON.

HAIR-BEARING SINUS

SIR,—In their article on the pathology of postanal pilonidal sinus (1946, ii, 484) Mr. Patey and Professor Scarff described a hair-bearing sinus found in a barber's hand. I recently encountered a somewhat similar case.

A man, aged 52, for many years a barber, came to hospital complaining of a painful swelling between the middle and ring fingers of the right hand. About six weeks previously he had noticed some hair-clippings lodged in a depression or fissure in the skin of the web, and had tried to remove them, using forceps, with apparent success. A week or so later he developed a painful swelling in this area, which had since varied a little in size. There was a red and tender swelling on the dorsum just short of the distal edge of the web between the 3rd and 4th fingers, surmounted by a small yellow area where a collection of pus was threatening to discharge. Extending proximally from it for about $^1/_2$ in. in the subcutaneous tissues was a firm and slightly tender track, which felt exactly like the tissue reaction around a retained wood splinter.

The hand was explored under general anæsthesia; using a tourniquet, the track was excised without much difficulty. During the dissection, however, it seems likely that the track was opened, for three fragments of hair, each about 3 mm. long, were discovered. Section showed a typical foreign-body granuloma with aggregations of giant-cells. No hair was found and (contrary to the findings of Patey and Scarff) there was no track lined with squamous epithelium or containing hair-follicles.

The patient had no hesitation in attributing his trouble to penetration of the skin by hair clippings, probably during the finger manipulations employed in shampooing, and he had known at least one of his fellow barbers to have an exactly similar lesion.

I am not convinced, however, that postanal pilonidal sinus results from penetration of the skin by hair from without.

Glasgow. M. R. EWING.

STEVENS-JOHNSON SYNDROME

SIR,—The articles of Dr. Nellen and Dr. Murray in your issue of March 15, and your annotation of March 22, prompt me to record two other cases of Stevens-Johnson syndrome, one of which supports your remarks on the possible confusion with smallpox.

CASE 1.—A boy, aged 10 years, admitted to Mile End Hospital on Oct. 23 and discharged on Dec. 3, 1930. The rash was of the target variety, described as erythema iris, containing a central vesicle or bulla. There was an outer bluish-red area encircling a paler zone, the central bulla again being surrounded by a ring of erythema. The lesions were most numerous on the legs, arms, and hands, being particularly plentiful over the anterior aspects of the knee-joints. Some lesions were present on the face and scrotum and there was severe involvement of the mouth and eyes. The trunk was only slightly affected. Recovery was gradual and uneventful, and as far as I can recollect there was no evidence of pneumonia.

An interesting feature was his readmission just over a year later (Dec. 18, 1931, to Jan. 5, 1932) with a recurrence of the condition. On this occasion the disease was much less severe and the rash was limited to a few spots on the limbs and face without much involvement of the mouth and eyes.

A number of investigations were carried out but no significant results were obtained. Unfortunately the notes have been destroyed but I have some photographs which recall the appearance and distribution of the lesions.

CASE 2.—A boy, aged 14 years, admitted on Nov. 24, 1946, and discharged on Jan. 9, 1947, whom I was called to see in the receiving ward because the medical officers had considered the diagnosis of smallpox. The skin lesions were, however, identical with those which I had seen in the other case sixteen years before. He gave a history of coryza a week previously. For two days he had complained of soreness of the mouth and eyes. The previous day his mother first noticed spots on his face and others on the body later in the day.

He appeared very ill and toxic. Temperature 102° F, pulse-rate 130, respirations 28 per min. There were many lesions showing superficial ulceration on the lips and in the mouth. The skin lesions were circular and of the erythema iris bullosa type, ranging in size from a large pin-head to an inch in diameter. Some bullæ contained pus; others were replaced by scabs. The distribution was on the lower part of the face, the neck, arms, and legs. The rash was copious on the lower abdomen and on the penis. There were no lesions on the palms or soles. Many rhonchi were audible in the lungs. Intense conjunctivitis and blepharitis were present and a severe balanitis with some urethritis developed in the course of a few days.

He was treated with injections of penicillin in oil, 125,000 units twice daily for eight days after an initial dose of 250,000 units. Penicillin cream was applied locally and 'Albucid' drops instilled into the eyes. Physical signs in the lungs persisted and suggested some basal pneumonia, which was confirmed by X ray but had completely cleared by Jan. 2. The pyrexia persisted for two weeks and during this period the pulse-rate was rapid (100 to 120 per min.). All the lesions subsided gradually and the patient was fully recovered on his discharge. In neither case was there any residual damage to the eyes.

Blood-count on Nov. 24, 1946: red cells 6,750,000 per c.mm., hæmoglobin 108%, white cells 8200 per c.mm., differential count normal.

Penicillin did not seem to have any specific effect, but I thought it of some value in limiting secondary sepsis and in preventing the development of incipient pneumonia.

In both cases the diagnosis of erythema multiforme (iris bullosa type) was made, and the appearance of the lesions was identical with that illustrated in Jacobi's *Atlas of Dermochromes* by Henry MacCormac (London, 1927, plate 1, fig. 1). Dr. G. B. Dowling, in a letter in THE LANCET of Dec. 14, 1940 (p. 759), describes what must surely have been cases of this syndrome; he refers to the resemblance of the lesions to erythema multiforme or erythema iris, and the impression remains, in the absence of any known ætiology, that Stevens-Johnson syndrome is a severe manifestation of that condition.

Mile End Hospital, London, E.1. W. GORDON SEARS.

use of sanatoria for so-called "minimal" lesions, particularly those not associated with symptoms, we shall see an even greater survival-rate of patients treated. True, in the sanatorium, which is concerned essentially with mental and physical rest, we can expect this; but we know that the lesions in some of these patients would have healed without any treatment, and (through ignorance) without the stigma of tuberculosis.

The mere detection by mass radiography of more cases of gross disease will contribute little to preventive medicine, since we already know of more such cases than we can do anything for. It is amazing what massive infection the person with a good resistance can withstand, and it is the contributions to the latter which will give us a reduction in the death-rate. We are assured by Dr. R. R. Trail (March 15) that even after discharge from a well-run modern sanatorium "the average patient has a bleak outlook. . . . Lessened function and ostracism soon undo the benefits of the sanatorium."

I believe that great mischief is done in the dictation of treatment by radiography; for the film is often interpreted by chest experts who have had no basic training in radiology and who often shun the coöperation of their colleagues. The radiographic appearances are treated *instead of the patient; and because of the doctrine* of "symptomless tuberculosis" the patient stands the risk of treatment for adventitious radiographic effects.

The more radiographs I see, the more I value the clinical evidence. Within the past month I have seen an induced paralysis of the right diaphragm in a patient who on admission had no symptoms, no cough, no sputum, no tubercle bacilli but a good appetite, and whose radiograph before the operation showed the right apex obscured by a ringlet of hair which produced a pseudo-cavity with much reaction around. Such events may be rare, but they are not without significance when evaluating the passages quoted in my letter of Dec. 28, though Dr. L. E. Houghton (March 8), "hoist with his own petard," now seeks retreat. The answer to the question put to me by Dr. F. A. H. Simmonds (Jan. 11) will be found in the quotations I have given.

Birmingham. JAMES F. BRAILSFORD.

ATELECTASIS FOLLOWING OPERATION

SIR,—I read with great interest Mr. Stringer's article of March 8. The investigation he describes was like one that I had begun myself on somewhat similar lines, but my investigation was interrupted by military call-up.

I have always felt that the seeds of postoperative pulmonary collapse are sown, so to speak, in the first few hours following operation, as Mr. Stringer has demonstrated. The clinical diagnosis of collapse cannot be made at all for at least 24 hours after operation, and often not for 48 hours. It is during this period that so much can be done, if the possibility of collapse is realised, to help the patient and prevent the unpleasant effects of atelectasis. In my opinion every patient who has had an anæsthetic lasting for more than a short time should be considered a candidate for collapse and *should be watched carefully. I heartily agree* with the suggestion of routine radiography 12 hours after operation, though it might possibly be somewhat troublesome to carry out; immediate treatment will usually relieve the collapse at once.

I do not agree that bronchoscopy need be considered in these cases, a much simpler treatment being to hand. A recent case illustrates what I mean.

I was attending, as a physician, a diabetic patient who was being operated upon for repair of a hernia. By 48 hours after operation the temperature had risen to 100° F. The man was intelligent and coöperative; he said he felt perfectly well, and in particular emphasised that he had no cough. On examination of the lungs, however, there was definite dullness with poor air-entry at one base. I then performed the manœuvre which I have used several times in these cases, laying the patient on his sound side, pressing hard on the affected side, and instructing him to cough vigorously. He at once coughed up a teaspoonful of purulent material, much to his surprise. I repeated the manœuvre two or three times and then examined the lung bases. The dullness had almost disappeared, and there was now air-entry; the patient admitted that he felt distinctly clearer in the chest. The temperature was normal next day and never rose again. I instructed the nurse to repeat the manœuvre 4-hourly for 24 hours, as is my custom in this type of case. The dull[illegible] had by this time completely disappeared, and the air-entry was normal. There is nothing new in this procedure, though I have been surprised how little it seems to be known.

Finally, I would like to emphasise again that patients with pulmonary atelectasis do not have a cough in the early stages; and it is waiting for the patient either to cough or to say he has a cough that causes delay in diagnosis.

Liverpool. RONALD ELLIS.

NURSING AND THE DOCTORS

SIR,—As I am myself a ward sister in just such an institution as your correspondent, "Sister-tutor," I would like to say something in defence of the E.M.S. hospital. Sister-tutor is indeed unlucky in hers. The nursing staff here are extremely happy in their country surroundings, and many of them are sorry when they have to return to their parent hospital and town life. They certainly share cubicles here, but are comfortably housed, and the sanitary arrangements are quite adequate. Living conditions everywhere in this country are just as difficult as they were during the war—in many cases more so. We in hospital are fortunate in many ways: the incident of the night nurse, here, who returned in the middle of her "nights off" to get warm during this cold spell, proves this I think. Again, our medical staff here, both senior and junior, are always helpful and considerate towards the nursing staff. Is not the case of the surgeon who failed to turn up to the lecture perhaps rather an isolated one?

WARD SISTER.

PROTEIN NEEDS

SIR,—In their article on the treatment of infantile pellagra T. and J. Gillman[1] say:

"The recent literature contains reports of the ineffectiveness of the majority of protein hydrolysates in the treatment of hypoproteinæmia in dogs (Madden et al. 1945). Severe hypoproteinæmia with œdema and anæmia has even been *produced* in pigs by feeding casein digests in a particular dietary setting (Cartwright et al. 1945). In the light of these findings the 60% case-mortality in our series of cases treated with protein digests is not difficult to understand."

It is a pity that such sweeping statements should be made without proper reference to the earlier work cited. Madden and co-workers[2] used a large variety of protein digests in their experiments and concluded that "certain protein digests given by vein may favor good production of plasma protein, as well as nitrogen and weight equilibrium over long periods in dogs subjected to plasmapheresis. These digests may be equally effective when given subcutaneously or intraperitoneally and more effective orally. Certain other digests may not be well utilized." What was evident from this and other investigations was that for optimum plasma protein formation the most important factor is the amino-acid make-up of the preparation, which in turn depends *upon the nature of the protein and the* methods employed for digestion and subsequent processing. An inadequate protein like gelatin or zein or an acid hydrolysate of casein as the sole source of protein can neither support growth nor promote plasma-protein production. Even if two proteins or amino-acid mixtures are equally effective for growth, one of them may be superior to the other as far as plasma-protein production is concerned. Madden and his associates have been trying to elucidate the specific amino-acid requirements *of plasma*-protein formation.

In the other paper referred to, Cartwright and his colleagues[3] were mostly concerned with a comparison of the anæmia produced in swine by feeding them a protein deficient in tryptophane and the anæmia caused by pyridoxine deficiency. For producing tryptophane deficiency they used zein and an acid hydrolysate of casein. Although casein is rich in tryptophane this is mostly destroyed during acid hydrolysis. *Using such* a hydrolysate and zein, they were able to produce severe anæmia, hypoproteinæmia, and œdema in experimental animals.

[2] *J. exp. Med.* 1945, 82, 181.
[3] *J. clin Invest.* 1945, 24, 268

But the usual protein hydrolysates intended for therapeutic purposes are prepared from proteins of high biological value, such as casein, lactalbumin, and meat, by enzymic digestion with which there is no destruction of any essential amino-acid. If an acid hydrolysate is used (mostly for parenteral use) it is fortified with tryptophane and cystine to make up for that lost during hydrolysis.

In the light of these facts the remarks of the Gillmans about protein hydrolysates in general are hardly justifiable. It is likely that in infantile pellagra the primary requisite is something contained in 'Ventriculin,' in the absence of which the administration of large amounts of protein or protein hydrolysates may further tax the already damaged liver. It would have been interesting to try ventriculin together with a good pancreatic digest of casein or papaic digest of meat.

COMPRESSION OF MEDIAN NERVE IN CARPAL TUNNEL

SIR,—Both Professor Harris and Mr. Roaf advocate immobilisation for compression of the median nerve in the carpal tunnel, and Professor Harris adds to the treatment the additional compression of a hard object in the palm. Experience shows, however, that when nerve-compression reaches the point of causing muscular wasting it cannot be cured by rest alone, for rest does not permanently remove the cause. Pressure neuritis of the slipping ulnar nerve does not recover unless the nerve is transposed, nor will either rest or exercises relieve the muscular wasting due to a costoclavicular syndrome. Indeed, in both these instances motor recovery is often incomplete after operation because operation has been undertaken too late. Similarly the swollen and fibrosing median nerve will not recover if after rest it is to be exposed to the same compression and the same traumatising movements as before—and working women cannot give up manual work for the rest of their lives. The danger of immobilisation is delay, for the longer the lesion is allowed to continue the less complete will be recovery of sensation and movement.

London, W.1. W. RUSSELL BRAIN.

DOCTORS' SALARIES

SIR,—As final-year medical students we naturally hope to receive a decent rate of pay for our work on qualification, but we strongly deprecate the attitude of those who suggest that being a doctor, *per se*, entitles one to about ten times the total wage of the majority of workers.

Many a man has to provide all that his family needs on £5 a week—how dare your correspondents consider themselves entitled to spend this much on food alone for two people?

Chief Assistant's wife must surely regard his letter as a slight on her competence as a housekeeper. We have catered for ourselves for four years, and therefore have a real knowledge of the cost of food. Now that one of us is married, she is able to feed herself and her husband on £2 10s. a week without undue difficulty; and this sum includes the cost of canteen meals.

ELIZABETH GORST
London, N.1. KATHLEEN CORBISHLEY.

THE PERIODICALS

SIR,—I am sorry to see your defence (March 15, p. 348) of the Periodical Proprietors Association's high-handed action in depriving the public of even those periodicals which would have escaped Mr. Shinwell's ban. This action seems to have been taken solely in the publishers' interests, and without any regard for those of readers.

One would like to have thought that THE LANCET at least would have considered its readers and its services to science in general as more important than its allegiance to the P.P.A., and would have defied the latter's ban, resigning membership if necessary. Certainly Thomas Wakley would not have submitted so meekly.

Witham, Essex. J. W. NICHOLAS.

_ Dr. Nicholas seems to misunderstand the sequence of events. The Government, faced with an indubitably dangerous situation, decided that industrial use of electricity must be virtually suspended for the time being. Exception was made for hospitals, catering establishments, and "newspapers," all of which were held to provide essential services; but no exception was thought necessary for periodical journals. The Government's instructions on the subject had no legal sanction, but were obeyed by all the many industries affected, including all printers. No journal therefore could continue its usual service to its readers. The possibility remained of publishing token issues produced without the use of electric power; but the Periodical Proprietors Association thought that if there must be a ban it should apply in the same way to all, and therefore approved the Government's instruction that hand-produced issues were not permitted. So far as we know, neither the association nor anyone else was acting "in the publishers' interests": for almost all journals the saving in costs of printing and distribution during the fortnight's suspension was far outweighed by the corresponding loss of advertisement revenue. As to the propriety of ignoring the instructions by way of protest, opinions will continue to differ. The fact that all ordinary newspapers were appearing as usual made it clear that the Government did not really intend or wish to muzzle the press; and at a time when the country as a whole was suffering so much damage we felt that complaints about the relatively small loss and inconvenience to our readers and ourselves would be out of proportion. If ever we are persuaded that the liberty of the press is seriously threatened we shall not be backward in its defence.—ED. L.

THE MEDICAL SCHOOL

SIR,—Your leader of Jan. 4 says that "the medical schools of Britain are capable of attaining and maintaining the highest technical standards." As a war-time student at one of London's most illustrious schools I certainly do not want to under-estimate the severe stresses under which our teachers have manfully been labouring. But I venture to ask why the vast potentialities of our medical schools, with their top-line specialists, first-rate laboratories and lecture-theatres, and hand-picked cases, are still so far from being realised.

I would point first, to the indifference of teachers to our individual presence or (understandable) absence at ward-round or lecture, and to our early difficulties in approaching the patient in his bed; secondly, to the fact that we have no systematic instruction in medicine or surgery (I can remember being hurriedly initiated by sister into the devious arts of scrubbing-up, five minutes before the beginning of the first operation at which I was due to assist); and thirdly, to the system whereby gold-medallist applicants for house-appointments are turned down in favour of rugger blues (by the simple expedient of asking one candidate how he would prepare a turpentine stupe, and the other which drug he prefers in penicillin-sensitive pneumococcal pneumonia). The idealism which uplifted so many of us at the inception of our careers becomes now a bitter relic of its former self.

We are not asking to be spoon-fed. We know we must go out and get knowledge for ourselves before it will stick. But it is a fallacy to believe that, now we have left school, we fare better if left to our own devices, and no longer need frequent signposts to the founts of wisdom. Spoon-feeding for the infant is admirable. A help-yourself service for the adult is economical. But neither is suitable for the adolescent. And it is the immature and the faltering among us who stand in most need of guidance.

May I put forward a few tentative suggestions?

(1) Let us have a say, however small, in decisions affecting our curriculum.

(2) Let us have smaller firms as soon as possible, with more frequent tutorials of the "fireside-chat" category by the registrar, houseman, or honorary, so as to approach the ideal of individual tuition, with which no other professional course is more inadequately provided. In this way will students feel themselves part of a cognate group working at a common task.

(3) Let us have system in our lectures, and, more important still, in outpatients. If full-time courses can be arranged in fevers, midwifery, and psychiatry at specialised institutions, why not in ear, nose, and throat, in ophthalmology, and in dermatology, reserving the parent hospital perhaps for more general work?

(4) Let us have more student house-appointments—a taste of responsibility to give us some idea of the difficulties of the staff, to turn our present parasitic apathy into symbiotic satisfaction, and possibly to turn out something useful. Aimlessly loafing through the hospital, vaguely drinking soul-destroying cups of coffee, tolerated at best by those around us who are fortunate enough to be employed, we would welcome with enthusiasm such opportunities to justify ourselves.

(5) Please, can we sit down somewhere in medical rounds of more than three hours' duration?

AMOS.

_ It has been suggested that shooting-sticks with rubber crutch shoes would make an ideal seat for students in ward rounds.—ED. L.

Parliament

ON THE FLOOR OF THE HOUSE

THE Budget is looming ahead. The House has therefore been considering the main bills and estimates concerned with the Services, and there have been debates on man-power and defence problems as a whole. In a world of military uncertainties the need for strong defence forces needs little argument, and we have big commitments not only in the United Kingdom and Western Europe but also in the Middle East and the Far East; yet we, and many countries of the world, are suffering from a man-power famine even though since the end of the war there has been a run-down of 3½ million workers in the munition industries and over 4½ million men and women have returned from the Forces to civilian life. A crucial item which allows for no diminution is our contribution to forces in the United Nations Organisation. Mr. Alexander, speaking as Minister of Defence, told the House that our Government are pressing, in the Security Council, for "swift and decisive" action to organise the forces which, under article 43 of the charter, are to be put at its disposal to prevent aggression. When National Service is the law of the land we shall have a stable force at our disposal to be our contribution to the United Nations Force. The Labour rebels who are against conscription thus find themselves refusing aid in setting up the international police force which is the essential guarantee of world peace and security. The defence of Great Britain and the Commonwealth will become, when countries of the Security Council and other nations are joined with it, the defence of the world.

But inside the framework of these great needs there are possibilities of economy of man-power in the work of new committees, partly military and partly civilian, which the Services have set up. Civil experts and military experts must look at Service questions from outside the four-square rules and regulations of Service procedure. Warfare now is total, so consideration of Service economy must be total also, and the civilian may have to muscle-in—sometimes in regions to which he has been unaccustomed.

MEDICUS, M.P.

FROM THE PRESS GALLERY

Control of Penicillin Bill

IN moving the second reading of the Penicillin Bill, in the House of Lords on March 18, the Earl of LISTOWEL briefly outlined the powers of the Bill.[1]

The controls to be imposed, he pointed out, were limited to the supply of the drug to the public and there would be no interference with the wholesale trade or the supply to doctors, hospitals, nursing-homes, organisations for medical research, or Government departments.

Lord STRABOLGI read a letter from Dr. E. W. Fish, which ran:

> "There is one danger which this Bill does not cover. If penicillin lozenges for the mouth may be prescribed in any quantity the practitioner thinks fit, there may be a large number of people who will give prescriptions for perhaps 100 at a time, and if their patients use them, possibly spasmodically, for some chronic complaint such as tonsillitis, or even a tendency to dental caries, the mouth and throat of such a person would be an ideal breeding ground for the resistant strain of streptococcus which might infect somebody else and prove fatal. I do not see how this could be prevented, except through the medical press pointing out the danger. One could, of course, limit the permitted sale of lozenges to some two dozen at any one time, or on any one prescription, but it would be difficult in factories where the nurse hands them out, I believe, under the doctor's orders, and Fleming felt, perhaps more strongly than I did, that no attempt should be made to go further than the present Bill provides."

Lord Strabolgi asked the Government if it would be possible to strengthen the Bill in these terms.

Lord AMULREE was satisfied that the medical profession would welcome the Bill but raised two points. Some firms were charging a greatly enhanced price for cosmetics which contained quantities of penicillin so minute as to be valueless. This was likely to bring the drug into disrepute. Again, penicillin snuff was good for the after-effects of colds and catarrh, and similar maladies. If this snuff was safe, Lord Amulree did not think there was the same reason for restricting its sale to a limited amount on each prescription. Penicillin snuff tended in a short time to lose its properties, and it was therefore hard to make a patient go back to his doctor for a fresh prescription each time he caught a cold. Surely it should be possible to get a repeat supply on the original prescription?

The Earl of MUNSTER drew attention to the words at the beginning of clause 2:

> "The substances to which this Act applies are penicillin and such other anti-microbial organic substances produced by living organisms as may be prescribed by regulations. . . ."

What, he asked, were those other organic substances which could be prescribed by regulations of four Government departments?

The Earl of LISTOWEL agreed that the point raised by Lord Amulree about the sale of what might be called "pseudo-penicillin" preparations by chemists was an additional argument in support of the Bill. In reply to Lord Strabolgi's point, he suggested that the responsibility for not prescribing too large a quantity of penicillin tablets at one time must fall upon the medical profession and was not one for the Government to enforce by statute. Lord Munster had also raised an important point. The Bill dealt with substances which were still largely in an experimental stage. The most advanced of these preparations, apart from penicillin, was streptomycin, on which the Medical Research Council were now conducting tests. The Government had come to the conclusion that too little was known about the properties of streptomycin to mention it specifically in the Bill. But provision was made for the making of regulations under the Bill when it was proved in accordance with laboratory tests that a certain substance had properties similar to penicillin and therefore should be subject to control.

QUESTION TIME

Production of Streptomycin

Dr. BARNETT STROSS asked the Minister of Health what weight of streptomycin was being manufactured each month in Britain; and what type of clinical trials were now being carried out by the Medical Research Council on the treatment of tuberculosis.—Mr. JOHN EDWARDS replied: The present production is very small but the Minister of Supply hopes that by June it will be about 250 grammes per month. The Medical Research Council has organised clinical trials at selected hospitals in certain types of tuberculosis cases.

Penicillin for British Zone

Mr. SOMERVILLE HASTINGS asked the Chancellor of the Duchy of Lancaster whether he was satisfied that the amount of penicillin supplied from official sources to the British zone of Germany, namely, 95 mega units a month, enough for 50 or 60 cases only, was sufficient for all needs apart from the treatment of venereal disease; and how many applications for supplies of this drug had been received by the public-health branch of the Control Commission from the German Public Health Advisory Committee which had not been acceded to. —Mr. J. HYND replied: No applications for penicillin have been made to the British authorities by the German Public Health Advisory Committee for some months past. I am advised that supplies made available by the relief societies alone have been sufficient to meet recent demands. It is likely, however, that the widening experience now being acquired by German doctors in the application of the drug will lead to a demand for larger quantities and it is planned to increase substantially the present monthly official allocation for non-V.D. cases.

Mr. HASTINGS: Will the Minister make it clear to the German doctors that more penicillin is available if it is required?—Mr. HYND: We are taking steps to encourage German doctors in the use of this drug and to obtain knowledge of its proper use. We anticipate that we will be able to meet any commitments likely to be made.

Obituary

JOSEPH BARCROFT

KT., C.B.E., M.A. CAMB., D.SC., HON. M.D., HON. F.R.C.O.G., F.R.S.

Sir Joseph Barcroft, the Cambridge physiologist, died suddenly on March 21 while returning home from his laboratory. He will be warmly remembered and widely missed, not least in the medical profession. Though his medical degrees were honorary, they were very properly bestowed on a man who gave so much of his mind and heart to clinical problems and did so much to inform and assist doctors. His scientific reputation is one that will endure and grow.

He was born on July 26, 1872, the son of Henry Barcroft, D.L., of Newry, Co. Down. The family were Quakers, and he was sent first to Bootham, the Friends' school at York. Thence he went to the Leys School, Cambridge, where he was one of a group of prefects almost all of whom attained distinction later: they included Henry Dale and John Clapham (simultaneously presidents of the Royal Society and the British Academy), F. A. Bainbridge the pathologist, H. C. Gutteridge the authority on international law, and Gibberd one of the last senior wranglers. At King's College, Cambridge, Barcroft took a first in both parts of the natural sciences tripos and was elected to a fellowship in 1900. For several years he worked as a master at the Leys School, but thereafter devoted himself entirely to physiology as university reader under J. N. Langley. He was elected F.R.S. in 1910; and succeeded in 1925 to Langley's chair, which he held till 1937. From 1941 until his death he was director of the Agricultural Research Council's unit of animal physiology.

As a physiologist Barcroft had three or four research careers, each enough to assure him fame. They began with his classical work on the oxygen carriage of the blood; and every student now learns about his blood-gas apparatus, his oxygen-dissociation curves, his classification of the varieties of anoxia, and his experiments disproving oxygen secretion in the lungs. Opposing J. S. Haldane in a long controversy, he maintained that the passage of gases through the alveolar-epithelium is a simple physical process, and that even under adverse conditions the lungs cannot take up oxygen unless the oxygen pressure in the air is higher than that in the blood. In support of this conclusion he exposed himself to low oxygen pressures for long periods inside a glass box at Cambridge and made experimental observations with a team which he took to the Andes for the purpose. His *Lessons from High Altitudes* is a study of acclimatisation.

During the war of 1914–18 he was asked to advise on poison-gas. Ready as ever to immolate himself if need be, he walked with his dog through a gas chamber filled with KCN in a concentration known to be lethal to dogs. The dog died, but Barcroft cycled home to advise against the manufacture of cyanide gas-shells. His association with the War Office, begun in 1917 as a member of its chemical warfare committee, continued as a member of the Army Medical Directorate consultative committee from 1928 to 1943.

Meanwhile his studies on altitude had attracted his attention to the spleen, and in a series of beautifully planned researches, with H. W. Florey, J. G. Stephens, and others, including observation of the spleen through celluloid windows, he demonstrated, inter alia, its storage function. From 1921 onwards he had been developing the concept of a blood-volume divided, in proportions fluctuating from moment to moment, between circulating and depot blood; and though the earlier literature contains some suggestions of this idea, and also some evidence for it, it was he who proved and published it adequately and made it a part of current doctrine. The concept was a major contribution to physiology.

It was probably this work on the blood-volume that led, via the blood-supply of the pregnant uterus, to Barcroft's studies of the fœtus, which in turn have done much to persuade others of the importance of prenatal physiology. Physiology begins with conception, but until recently nobody seemed to be much interested in what happens in utero, though the study of that period of life provides clues which can help to resolve many postnatal mysteries. In biological research the main difficulty is to reduce variables, and this difficulty is to some extent surmount in intra-uterine studies, because one can select s of development in which the organism has not y acquired its postnatal complexity. For example, effects of carbon-dioxide excess can be determined various centres in the brain are properly developed, one can note the reactions of the circulatory sys when it is not yet under the control of a nerve-supply. A generation hence, physiology textbooks are likely to begin with a long section on embryonic and fœtal function, and it is to be hoped they will give due credit here to the greatest figure among the pioneers.

Last October Barcroft published the first volume of his *Researches on Pre-natal Life* (Blackwell Scientific Publications), and in its preface he wrote:

> "This work partakes very much of the nature of a will —I hope not my last. . . . The general aim . . . of this book is to trace the development of function in the mammalian fœtus, never losing sight of the fact that one day the call will come and the fœtus will be born. Not only has the fœtus to develop a fundamental life which will suffice for intra-uterine conditions, but at the same time it has to develop an economy which will withstand the shock of birth, and will suffice, nay more than suffice, for its new environment."

From 1937 to 1939 Barcroft and D. H. Barron at Cambridge had coöperated with A. E. Barclay and K. J. Franklin at Oxford in cineradiographic studies of the fœtal circulation, and their joint efforts secured objective records where hypothesis had been dominant for three centuries. In *The Brain and its Environment* (1938) he had built on Claude Bernard's conception of the "milieu interieur," the book being largely based on the effects of environmental changes on the fœtal nervous system. More directly addressed to the practising doctor were his Sharpey Schafer lecture at Edinburgh in 1941 on Four Phases of Birth, and his Linacre lecture at Cambridge in 1942 on the Onset of Respiration at Birth, with comments on resuscitation.

As a lecturer Barcroft had early proved his skill, and his many addresses to many audiences were not least among his services. He had the gift of explanation; he spoke to an audience in the interesting way in which he would speak to a friend; and he used an imaginative humour. "I have no wish," he remarked, "to deny that the spleen is an important cemetery for red blood corpuscles any more than I have to tilt against anyone expressing the view that London is the largest cemetery in England." Again, on Physical Unfitness in relation to Density of Population: "Something is wanted comparable to 'hunger' which impels people to take exercise. Probably in some obscure form it is there, but it needs cultivation in a sense which hunger does not. Probably the healthier the youth of this country the more anxious they will be to be out and about, so that you start with the advantage of a benign circle." One of many brilliant addresses published in these columns was his Stephen Paget lecture of 1934, discussing Experiments on Man—a subject on which he had ample right to speak.

Sherrington in his *Man on his Nature* remarks that "we dismiss wonder commonly with childhood. Much later when life's pace has slackened, wonder may return. The mind then may find so much inviting wonder, the whole world becomes wonderful." Perhaps Barcroft's outstanding characteristic was that he never lost this childhood's wonder, and thus he secured a constant driving force for many grown-up thoughts. He always seemed to be able to step out of the ruts of contemporary ideas and research and roam freely, alone or with some chosen companions, seeing wonders that were invisible to others. Then he would return to report on what he had seen and done—talking in that simple, exciting, slightly breathless way he had, making all he had discovered seem so self-evident, poking fun at himself, and generously paying tribute to his collaborators. Like other people, he was not omniscient; indeed his reputation occasionally suffered because he was not afraid, in discussions, to put forward some idea which others knew to be unfounded. Yet he had the knack of seeing the "story" in a problem, and his terrifying disregard for details—some details—was justified by his proving so often right. He seemed to back his h [illegible] against the perverseness of nature, but his success was really due to his ability to see the problem in its simplest elements where others saw only a mass of work to be done.

As an experimenter he was imperturbable, and he followed the principle that each experiment should attempt to answer only one question: he was content with a small plus provided it was permanent, and in this he showed his patience, his thoroughness, and also his vision. He had his long-distance plan and achieved it gradually but with certainty. When, at nearly 70, he took over his new appointment with the Agricultural Research Council he began planning investigation of the digestion and metabolism of ruminants. He would say, "Of course I know nothing about it"; but somehow he seemed to know enough to launch work which has already yielded many important results. With his death a vital spark has gone out of British physiology.

He treated everyone with a courtesy and understanding which seemed to be based on an inner conviction that the good in them was the only thing worth bothering about, and this made him a fine collaborator. 'He seemed," says a colleague, "to be searching for somehing fundamental, both in his work and in people, which he felt ought to be there. Something certainly kept him resh and enthusiastic to the end."

Prof. A. V. Hill writes: "By the death of Sir Joseph Barcroft the world has lost one of its really great men. Viewed from a single aspect, the greatness of his stature may not be so apparent; but taking his whole life together, his outstanding contributions, practical and fundamental, to science and medicine, his services to Britain and her allies in two wars, his deep influence on all who knew and loved him, and the harmony of all his adjustments (befitting a good physiologist!) make no lesser estimate possible.

"The integrity and loyalty, the courage and humility, the wisdom and simplicity of 'J. B.'s' character: his thoughtfulness for others combined with inflexibility of aim and principle; his seriousness of purpose adorned with the grace of gaiety and laughter; his intuitive understanding of men and affairs; his experimental skill and persistence: the enchantment of his home, the romantic qualities of his speech and writing, the magic which set people at once to profitable jobs around him; the charm and steadfastness of his friendship, the generosity of his helpfulness: these all, and one could say much more, gave him a unique position among physiologists and an exceptional place in general affection and esteem. Workers in physiology, nutrition, and agriculture, and in human and veterinary medicine, soldiers and airmen, mountaineers, and sailors whether in big or little ships, all are in debt to J. B. 'After all,' he wrote in 1913 in the preface of *The Respiratory Function of the Blood*, 'the pleasantest memories of a cruise are those of the men with whom one has sailed. The debt which I owe to my colleagues. . . . will be evident enough to any reader of this book. It leaves me well-nigh bankrupt—a condition well known to most sailors.' That kind of bankruptcy is indeed well known reciprocally to all who have sailed with J. B.

"In the same preface he wrote: 'At one time . . . most of my leisure was spent in boats. In them I learnt what little I know of research, not of technique or of physiology but of the qualities essential to those who would venture beyond the visible horizon.' Those qualities, call them intuition or what you like, were evident in all he did; but they were backed by splendid patience, by fine judgment, and indomitable hard work. The same imaginative qualities and the same capacity for new work lasted unabated to the end. Nearly ten years after formal retirement he was chairman of the Food Investigation Board, head of a unit of the Agricultural Research Council for research in animal physiology, chairman of the sectional committee of physiology and medical science of the Royal Society—and active in many other ways. He died suddenly, aged 74, going home from his work: happy in his ending, except for the sorrow he has left behind.

"It is impossible to think of J. B. apart from his home. Lady Barcroft, the daughter of Sir Robert Ball the astronomer, inherited her father's sense of fun, and the laughter which, like a nosegay, decorated their joint lives made them the most perfect partners and the most perfect hosts. They realised that the most serious things can often be better said and done gaily—and they said and did them so. They provided, for many years, a centre for the physiologists of Cambridge and (on occasion) of a wider circle. Lady Barcroft is a joint creditor with J. B. in what we owe.

"I do not know how many pupils J. B. had, but it must be hundreds, from most of the countries in the world. Their careers generally show more than a sign of his handiwork. He was regarded with the same esteem in the United States and many other countries as in England. He loved, and was loved in, King's. He was a great ambassador for the fellowship of scientific men everywhere: he will be mourned throughout that fellowship and throughout the world.

Sir Joseph Barcroft was appointed C.B.E. in 1918 and knighted in 1935. He received honorary degrees in science from Harvard, from Queen's University, Belfast, from the National University of Ireland, and from Trinity College, Dublin, and in medicine from Sofia and Louvain universities. The Royal Society bestowed on him its Royal, Baly, and Copley medals, and he was Fullerian professor of physiology at the Royal Institution from 1923 to 1926.

Of his two sons, one is Dr. Henry Barcroft, professor of physiology at Queen's University, Belfast.

GEOFFREY DUCKWORTH

M.R.C.P.

Dr. Geoffrey Duckworth, physician in charge of the skin department of the Bolingbroke Hospital, and physician to the St. John's Hospital for Diseases of the Skin, died at his home at Wimbledon on March 18. In 1929 he qualified from St. George's Hospital and he took his M.R.C.P. three years later. After serving as registrar to both the inpatient and outpatient departments of St. John's Hospital he was appointed to the staff ten years ago. In all the affairs of the hospital he showed great interest, and he will be missed from its committee meetings, which he regularly attended. He was also a member of the staff of the Royal Hospital and Home for Incurables at Putney, and an assistant editor of the *British Journal of Dermatology and Syphilis*. During the war he acted as a physician dermatologist in the E.M.S.

A keen investigator, Duckworth often brought difficult cases to one of his colleagues for discussion; and, writes R.T.B., "This was made easy by his natural humility, a quality which greatly added to his charm. New aspects of therapy and all possible advantages for the comfort and progress of his patients were certain to stimulate his enthusiasm. He never sought the limelight, and was often too diffident to enter the discussions at society meetings, but we who knew him held him in great respect and friendship."

Dr. Duckworth leaves his wife with two daughters and a son. He was 46 years of age.

WILLIAM THOMSON MUNRO

M.D., LL.D. ST. AND., F.R.C.P.E.

William Munro was medical superintendent of Glenlomond Sanatorium, Kinross, for 25 years. Yet his position in tuberculosis is difficult to define. He always claimed to be a clinician and he studied the disease from that angle. It was thus that he saw its problems, and the value of his contributions to the subject lay primarily in the fact that they were deliberate investigations of problems seen in the course of his daily work. But despite his own claim to clinical interest his happiest hours were spent in his laboratory—a small room containing the minimum of equipment. Here work was done in the best tradition by a man who wanted to know why; and when he retired owing to ill health in 1945 he had in mind several inquiries to which he knew no satisfactory answer.

He graduated M.B. with distinction at St. Andrews in 1908 and M.D. four years later. After holding house-appointments at the Royal Infirmary, Dundee, he took his D.P.H. in 1914. A period of war service followed, and in 1920, after his demobilisation, he was appointed to Glenlomond Sanatorium.

One of the original members of the Tuberculosis Society of Scotland, Munro probably contributed more to that society than any other member, and he served as president from 1935 to 1938. In 1929 he was elected

F.R.C.P.E. and he was surprised and delighted when his own university in 1945 conferred upon him the degree of LL.D.

"Essentially an individualist, Munro tackled his own problems," writes C. C., "but he acknowledged the help and work of others and he was undoubtedly influenced by Robert Philip, Stanley Griffith, Bruno Lange, and Calmette. His investigations covered a wide field, but his best-known work is that on phthisis of bovine origin and on tubercle bacilluria. He had faith in his own views, which he expressed with conviction, and although in debate he often disagreed strongly with the views of others a spark of pawky humour illumined his remarks and no sting remained.

Sometimes he had the appearance of being aggressive, but he was a kindly man, shy at heart, and generous in his estimate of those whose work was more to them than a mere job. The lazy and garrulous were anathema to him, and there were no humbugs among his friends."

Dr. Munro's brief retirement was spent at Kinross, where his wife died 18 months ago. They had no children.

FREDERICO NITTI

Dr. Nitti was the son of Signor Francesco Saverio Nitti, prime minister of Italy before the advent of Mussolini. For many years he was in charge of the bacteriological side of the chemotherapy investigations at the Pasteur Institute in Paris, and he was one of the team who first found the activity of sulphanilamide in streptococcal infections.

After Domagk's discovery of the activity of 'Prontosil,' which was published in 1935, Prof. J. Tréfouël, Mme. Tréfouël, Nitti, and Bovet immediately started to assay a series of similar diazo compounds in mice infected with streptococci. After nine months' work they noticed that all of the diazo compounds which included the residue of the sulphanilamide group were active, whereas those without this grouping had no activity; further it was seen that no great change of activity resulted from changes in the other primary amine forming the diazo compound. They then tried sulphanilamide itself and found it to be active. This finding, following Domagk's discovery of prontosil, pointed the way to the great development of the chemotherapy of bacterial infections during the last decade. Nitti continued his chemotherapeutic research both with the antibiotics and with synthetic chemical substances, and took part in the very wide clinical trials at the Pasteur Hospital. His enthusiasm for this work was a most valuable asset to the Pasteur team.

He was a charming and delightful colleague, and his early death on March 1 is a loss to medical science. He had been suffering from tuberculosis for the past two years, but was only recently persuaded to give up his work.

Dr. RICHARD RICE died on March 7 at his home at Harwell, where he was in practice from 1882 till his retirement in 1945. A keen follower of the Old Berks Hunt, in the early days many of his rounds were done on horseback or by dogcart. On his 80th birthday 250 of his friends and patients presented him with an album of autographs.

Appointments

EVANS, W. J. M., M.B. Lond., D.P.H.: M.O., Tanganyika, Colonial Service.

HAMILTON, WINSTON, M.B. Belf., D.P.H.: asst. tuberculosis officer, West Riding, Yorks.

JONES, MAXWELL, M.B. Edin., M.R.C.P.E., D.P.M.: consultant in medical psychology, British Postgraduate Medical School, London.

STUNGO, ELLIS, L.R.C.P.E.: clinical asst., department of psychological medicine, University College Hospital, London.

WHALLEY, G. H., M.B., B.HY. Durh., D.P.H.: T.O. and deputy M.O.H., Great Yarmouth.

WALSH, W. M., M.B. N.U.I., D.P.H.: medical superintendent, Maiden Law Central Isolation Hospital, Lanchester, Durham.

Examining Factory Surgeons:

FRANKS, SAMUEL, M.B. Manc.: Tyldesley, Lancs.
HARRISON, D. G., M.B. Dubl.: Shanklin, Isle of Wight.
HUNT, J. G., M.B. Lond.: Arundel, Sussex.
MACDONALD, DUNCAN, M.B.E., M.B. Glasg.: South Uist no. 1 district.
MACKINNON, GEORGE, M.B. Glasg.: South Uist no. 2 district.
ROSE, J. V., B.SC. St. And., M.R.C.S.: Newton Abbot, Devon.
WRIGHT, WINIFRED, M.B. Lond.: Shepton Mallet, Som.

Notes and News

FEES PAYABLE BY LOCAL AUTHORITIES

LAST year the representative body of the British M Association proposed a scale of fees for sessional or occa work undertaken by doctors for local authorities. This now been considered by a conference held under the ship of Sir William Douglas, secretary of the Ministry Health, at which an amended version was accepted by sentatives of the B.M.A., the County Councils Asso the Association of Municipal Corporations, the Urban Dis Councils Association, the Rural District Councils A the London County Council, the Association of Committees, the Mental Hospitals Association, and the politan Boroughs Standing Joint Committee. The scale approved, which is published in detail in the Supplement the *British Medical Journal* of March 22, is as follows:

For sessions at hospitals and clinics of, normally, 1½–2 hours, *the fee should be £4 4s. for consultants and £2* for general practitioners; and for sessions not exceeding 1 hour, £2 12*s.* 6*d.* and £1 10*s.* respectivel "Higher remuneration should be paid where senior con are required for work carrying special responsibilities." W payment is made on the basis of single cases the fee for surgeon should be not less than £5 5*s.* for a minor and £10 10*s.* for a major operation, his fee for a consultation being £4 4*s.* The minimum fee for the administration of an anæsthetic should be £1 10*s.* To consultants' fees should be added an allowance of 1*s.* a mile each way for every mile beyond two miles from the doctor's home or the centre where he practises (whichever is less).

General practitioners should receive 7*s.* 6*d.* for each antenatal or postnatal examination, or 12*s.* 6*d.* if a report is required by the local authority. For diphtheria immunisation 3*s.* 6*d.* *should be paid per injection at surgery, or* 6*s.* 6*d.* at the child's home, the material to be supplied by the local authority.

The rate of remuneration for other services should be arranged after consultation between the local authority and the local division of the B.M.A., and differences can be referred to the advisory committee set up under the Askwith agreement. It is also pointed out that nothing in these recommendations prevents a doctor from continuing his present contract with a local authority.

The revised scales operate retrospectively from Nov. 1, 1946. The agreement is "of an interim character," without prejudice to any future negotiations.

A CAUSE OF TALIPES

Hippocrates suggested that congenital malformations were due to intra-uterine pressure, but it was left to Browne[1] to work out the details of this mechanism for congenital talipes and some other deformities. Now Rebaudi and Iannuzzi,[2] of Addis Ababa, suggest that in some cases talipes may be caused by a foot getting caught in a loop of the cord. They support their argument with photographs of three seven-month fœtuses in each of which the cord is looped round the ankles. Unfortunately it is not possible to make out the exact condition of the feet. The report mentions six such cases studied in fœtuses delivered at the sixth to eighth month.

SOCIAL MEDICINE AT OXFORD

THE Institute of Social Medicine in its second annual report records that with coöperation of town and gown useful progress has been made during 1946. Investigations relating to the beginnings of life have included statistical studies of stillbirths, and clinical, radiographical, and social studies of *the pre-school child and adolescents. Studies* into occupational mortality, morbidity, and accidents have also been undertaken and research has been carried out into the epidemiology and ætiology of social diseases, such as tuberculosis, rheumatic fever, peptic ulcer, and cancer. This work continues, and a new project which has been started is a long-term study of student health at a men's and a women's college, with which is linked a health advisory service for the students. At the beginning of the 1946–47 session Prof. John Ryle, the director of the institute, was asked to organise all teaching in social medicine and public health for students during their clinical period. A course has been arranged

1. Browne, D. *Lancet*, 1934, ii, 960.
2. Rebaudi, F., Iannuzzi, V. *Boll. Soc. ital. Med. Igiene trop. (Sez. Eritrea)*, 1946, 6, 217.

which pays close attention to social factors in ætiology, and he lecturers besides the staff of the institute will include members of the city and county public-health departments.

CUT IN ALCOHOL SUPPLIES

THE production of drugs is likely to be seriously interrupted by a cut in the April allocation of alcohol to the manufacturers. The February allocation was reduced to 75% of the normal. In March this was made up by an allocation of 125%, but the drug firms were warned that this might have to cover April also. The Board of Trade has now informed them that there will be no April allocation. The reason given is the fuel cut to 33⅓%, which the alcohol industry is suffering in common with other industries. Like smelting, alcohol distillation is a process in which there is a close relation between fuel and output.

University of Oxford

A Betty Brookes fellowship for research into brain metabolism in relation to nervous and mental disease is shortly to be awarded. The fellowship will be tenable in the first instance for three years, and the stipend will be between £500 and £850 per annum. Application should be sent to the Whitley professor of biochemistry, University Museum, Oxford, not later than May 31.

Subject to the approval of convocation, the honorary degree of D.SC. will on May 1 be conferred on Dr. J. Tréfouël, director of the Pasteur Institute, Paris.

University of Cambridge

On March 15 the following degrees were conferred:

M.D.—J. W. Crofton, * F. S. Maclean.
M.Chir.—A. S. Till.
M.B., B.Chir.—* W. B. Webb.

* By proxy.

University of London

Dr. E. T. C. Spooner has been appointed to the university chair of bacteriology and immunology, tenable at the London School of Hygiene and Tropical Medicine, as from Oct. 1, 1947.

Dr. Spooner studied medicine at Cambridge and St. Bartholomew's Hospital, where, after qualifying in 1927, he was house-physician. Since 1931 he has been demonstrator and subsequently lecturer in pathology at Cambridge, where he is a fellow and tutor at Clare College. From 1940 to 1943 he worked for the Medical Research Council, becoming in 1942 member of a research section in the R.A.M.C. He graduated M.D. in 1942. From 1943 to 1944 he was director of the E.P.H.L.S. laboratory at Cambridge.

Dr. R. H. S. Thompson has been appointed to the university chair of chemical pathology, tenable at Guy's Hospital medical school, as from Oct. 1, 1947.

Dr. Thompson was trained at Oxford and Guy's Hospital, graduating M.A., B.SC., and B.M. in 1937. He held an Adrian Stokes travelling fellowship at the Rockefeller Institute of Medical Research, New York. In 1938 he was elected to the Gillson research scholarship in pathology by the Society of Apothecaries, and since then has been fellow and tutor of University College, Oxford, and demonstrator in biochemistry at Oxford. During the war years he was attached to the Chemical Defence Research Department of the Ministry of Supply, from 1939 to 1944, and from 1944 to 1946 he served in the R.A.M.C. with the rank of major. Since his return last year he has been dean of the medical school at Oxford.

Dr. H. Grüneberg has been appointed to the university readership in genetics, tenable at University College, as from Oct. 1, 1946.

From 1932 to 1933 Dr. Grüneberg was demonstrator in anatomy in the University of Freiburg. From 1933 to 1936 he was research student and since 1936 honorary research assistant at University College. Since 1938 he has held the Moseley research studentship of the Royal Society. He served in the R.A.M.C. from 1942 to 1946.

University of Sheffield

Dr. D. O. Stevenson has been appointed honorary lecturer in venereal diseases; Dr. Cynthia Redhead, tutor in child health; and Dr. S. J. Barr, assistant tutor in obstetrics.

University of Leeds

Dr. H. G. Garland has been appointed honorary demonstrator in neuropathology.

University of Edinburgh

On Tuesday, April 22, at 5 P.M., Dr. C. H. Kellaway, F.R.S., director-in-chief of the Wellcome Research Institution, London, is to deliver the 7th Sharpey Schafer lecture in the University New Buildings, Teviot Place. He will speak on the Perfusion Experiment in the Study of Tissue Injury.

University of Manchester

Among those who will receive honorary degrees on founder's day, May 21, will be Prof. E. D. Adrian, O.M., on whom the D.SC. will be conferred.

Auxiliary Royal Army Medical Corps Funds

The annual general meeting will be held at 11, Chandos Street, London, W.1, on Monday, April 14, at 5.30 P.M.

Westminster Hospital

The medical school of the hospital holds a clinico-pathological demonstration on the first Monday of each month, at 5 P.M. Owing to Easter the April meeting will take place on Monday the 14th.

Royal Medical Benevolent Fund

Messrs. Burroughs Wellcome and Co. Ltd. have handed over to the fund all proceeds of the sale of their medical diary for 1946. The gift, amounting to £650, will provide extra comforts for the fund's beneficiaries.

Charing Cross Hospital

Since 1911 students of Charing Cross Hospital medical school have attended King's College in the Strand for their anatomy and physiology. But next October, when it is hoped that repairs for bomb damage will be completed, the school will reopen its preclinical department, and this will enable it to take an additional 45 students each year. The preclinical school will be open to women as well as men, and opportunity is being taken at the same time to admit women to the clinical course. All vacancies for men for next session have already been filled, but applications from women may now be submitted. Further particulars will be found in our advertisement columns.

Epsom College

The council of the college will shortly award St. Ann's scholarships to girls attending Church of England schools. Candidates must be fully 9 and under 16 years of age, and must be orphan daughters of medical men who have been in independent practice in England or Wales for not less than 5 years. The value of each scholarship is dependent upon the means of the applicant and the locality and fees of the school selected.

Pensions are also available from the fund of the Royal Medical Foundation for impecunious medical men or their widows, and foundation scholarships, providing education, clothing, and maintenance free of cost for the sons of necessitous medical practitioners. Application forms are available from the secretary, Epsom College, Surrey.

North London Hospitals

Negotiations have now been completed for a scheme of close coöperation between the Prince of Wales's General Hospital and the Bearsted Memorial Hospital. The Prince of Wales's, with 260 beds, is the largest voluntary hospital in North-East London and is scheduled as a district hospital in the Ministry of Health Hospital survey. The new buildings of the Bearsted Hospital, to be opened in July, will have 100 maternity beds, and it is proposed that in addition to the general medical and surgical services already provided by the Prince of Wales's the two hospitals will offer a complete obstetrical and gynæcological service for the district. Both hospitals will also become part of the North London Postgraduate Medical Institute which also includes the North Middlesex County Hospital, the Chase Farm Hospital, and the North-Eastern Fever Hospital.

Centenary of the Chemical Society

The celebrations of the centenary of this society, which but for the war would have been held in 1941, will take place this year in London from July 15 to 17. Prof. C. N. Hinshelwood, F.R.S., the president, will open the centenary exhibition at the Science Museum, South Kensington, S.W.7, on Monday the 14th. The exhibition, which will remain open until the end of September, is to illustrate the development of chemistry in Great Britain and its place in the everyday life of the community. On Tuesday the 15th the visitors from overseas will be entertained to luncheon by the Government, and in the afternoon the president will deliver the centenary address. On the following day lectures will be given by Prof. E. K. Rideal, F.R.S., and Sir Robert Robinson, P.R.S. Further information may be had from the secretary of the society, Burlington House, Piccadilly, W.1.

Register of Orthoptists

The 1946–47 edition of this register has now been published, and doctors may obtain a copy free on application to the registrar of the Board of Registration of Medical Auxiliaries, Tavistock House North, Tavistock Square, London, W.C.1.

Allowance of Bacon to Tuberculous

On the advice of the Food Rationing (Special Diets) Advisory Committee, the Minister of Food has decided that persons suffering from active tuberculosis and actinomycosis, who are granted a priority supply of milk, shall also be granted an additional allowance of 1 oz. of bacon weekly in order to restore to them the recent cut in the ordinary consumer's bacon ration from 3 oz. to 2 oz. a week. These invalids are being invited at present to apply at local food offices for the additional allowance. In future the medical certificate of classification will provide the necessary authority for issue.

Fellowships in Plastic Surgery

Sir Simon Marks has established three fellowships, each to the value of £740 per annum, tenable for two years at the Queen Victoria Hospital, East Grinstead, Sussex. During the war with gifts from Canada, Australia, New Zealand, and South Africa, the buildings and equipment of the hospital have been modernised, while a new surgical wing has been given by the British War Relief Society of America. The "Simon and Matilda Marks fellowships in plastic surgery" will ensure that these facilities will be used for postgraduate education. Further particulars will be found in our advertisement columns.

Mackenzie Mackinnon Research Fellowship

Applications are invited from doctors for this fellowship which will be awarded in the form of grants to assist research in medicine or surgery and may be whole-time or part-time. The honorarium will be at the discretion of the joint committee of the Royal College of Physicians of London and the Royal College of Surgeons of England, and will be from £500 per annum according to experience and the amount of time available for research. A grant for expenses may be paid to the institution where the research is carried out. Applications must be submitted through a medical school by April 18. Application forms may be had from the secretary, Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2.

Hostel for Sanatorium Nurses

The British Legion has bought St. Alban's Guest-house in Colchester for use as a home for the nurses employed at Nayland Sanatorium, which lies 9 miles outside the town. Each nurse will have a separate room and there will also be a lounge, games room, and dining-room. Those responsible feel that they are taking a stage further the Rushcliffe Committee's recommendation that nurses should be able to go into town for recreational trips. The Nayland nurses are to live in the town and be transported to and from their work at the sanatorium.

Conference on the Family

A conference on Education for Family Life will be held in Manchester on April 21 and 22 by the extramural department of the university, assisted by the British Social Hygiene Council. The course is intended mainly for teachers and welfare workers, but will also be open to members of the public. Lectures will be given by Dr. Ethel Dukes, of the Marriage Guidance Council, Mr. Cyril Bibby, and Mr. R. Weatherall, educational secretary of the council. Further particulars may be had from the director of extramural studies, The University, Manchester, 13, or from the secretary of the council, Tavistock House North, Tavistock Square, London, W.C.1.

Nuffield Rheumatism Fellowships

The Nuffield Foundation is prepared to receive applications for these fellowships from medical men and women who wish to obtain advanced training to enable them to specialise "in the diagnosis, treatment and study of chronic rheumatism." The annual value of a fellowship will be between £500 and £800, with an additional grant for travelling expenses abroad where necessary. Candidates should have spent at least one year since qualification in the general medical practice of a hospital and should preferably hold the M.R.C.P. Service officers may apply for fellowships to be tenable on their release from the Forces. Further particulars will be found in our advertisement columns.

Cancer Research Congress

The programme of the fourth International Cancer Resear Congress, which is to be held at St. Louis, Missouri, fro Sept. 2 to 7, will cover the general biology of cancer, ætiolo (viruses, chemical carcinogens, hormones, and environmental factors), biochemistry, radiotherapy, and the development of nuclear physics, chemotherapy, and various clinical aspects. Further information may be had from Prof. Alexander Haddow, Chester Beatty Research Institute, *The Royal Cancer Hospital (Free), Fulham Road, London*, S.W.3.

THE Spanish review *Psicotecnia*, of Madrid, is to cease publication under that title, its place being taken by two new periodicals: *Revista de Psicologia General y Aplicada* and *Boletin de Psicotecnia*.

Diary of the Week

MARCH 30 TO APRIL 5

Monday, 31st

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Sir Cecil Wakeley: Surgery of the Thyroid Gland.

Tuesday, 1st

ROYAL COLLEGE OF SURGEONS
5 P.M. Dr. J. F. Brailsford: Bone Tumours.

Wednesday, 2nd

ROYAL COLLEGE OF SURGEONS
5 P.M. Dr. Brailsford: Bone Tumours.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
2.30 P.M. *History of Medicine.* Mr. N. M. Matheson, Mr. W. J. Bishop: Exhibition of Medical History in Postage Stamps. Dr. W. H. McMenemey: James Johnstone the Elder and James Johnstone the Younger of Galabank and Worcestershire.
8 P.M. *Surgery.* Mr. A. H. McIndoe: Dupuytren's Contracture. Mr. Richard Battle: Plastic Surgery in the Treatment of Chronic Ulcer of the Leg. Mr. D. N. Matthews: Tattooing in Plastic Repair.

Births and Deaths

BIRTHS

BATTLE.—On March 19, at Woking, the wife of Mr. Richard Battle, F.R.C.S.—a son.

DUDGEON.—On March 16, in London, the wife of Dr. Alastair Dudgeon—a son.

FLOYER.—On March 12, in London, the wife of Squadron-Leader M. A. Floyer, M.B.—a son.

GODBER.—On Feb. 10, at Kuala Lumpur, Malaya, the wife of Dr. Greville Godber—a daughter.

HAMBLING.—On March 12, at Woking, the wife of Dr. John Hambling—a son.

JENNINGS.—On March 12, in Dublin, the wife of Dr. O. B. Jennings, Colonial Medical Service—a daughter.

LISTER.—On March 18, at Newcastle-on-Tyne, the wife of Surgeon Lieutenant James Lister—a daughter.

RIDLEY.—On March 18, the wife of Mr. Frederick Ridley, F.R.C.S.—a daughter.

RONALD.—On March 15, the wife of Dr. James Ronald, of Stirling—a daughter.

SHAW.—On March 15, at Colchester, the wife of Dr. J. P. Shaw—a son.

SHEERS.—On March 16, at Tunbridge Wells, the wife of Dr. Geoffrey Sheers—a son.

VULLIAMY.—On March 18, in London, the wife of Dr. D. G. Vulliamy—a son.

WILDE.—On Feb. 24, the wife of Dr. J. F. Wilde.—a son.

WINNER.—On March 18, in London, the wife of Dr. H. I. Winner—a son.

DEATHS

BARBER.—On March 15, in London, Frederic Samuel Barber, M.R.C.S., aged 86.

CRICHTON.—On March 19, at Fordwich, Kent, Arthur John Moncrieffe Crichton, M.B. St. And.

DUCKWORTH.—On March 18, in London, Geoffrey Duckworth, M.R.C.P., aged 46.

GREG.—On March 17, at Carnforth, Arthur Hyde Greg, O.B.E., M.B. Camb., F.R.C.S., aged 75.

GROSVENOR.—On March 17, at Arnside, Westmorland, William Clayton Grosvenor, M.A. Glasg., M.D. Edin., F.R.C.S.E., aged 80.

MACKENZIE.—On March 13, at Virginia Water, Stephen Morton Mackenzie, M.A., M.B. Camb., aged 86.

MORTON.—On March 21, in London, James Livingstone Morton, M.B. Belf., aged 47.

MOXON.—On March 8, at St. Jacques, France, Herbert William Moxon, B.A. Camb., M.R.C.S., aged 65.

NEILAN.—On March 16, at Scarborough, John Alexander Neilan, L.R.C.P.I., D.P.H.

PARRY.—On March 20, in London, Herbert Lloyd Parry, M.R.C.S., aged 86.

SHARPE.—On March 15, at West Keal, Lincs, William Salisbury Sharpe, M.D. Durh., F.R.C.S.I., M.R.C.P.

TUDOR.—On March 14, at Leamington Spa, Dorothea Mary Tudor, M.B. Durh.

CLINICAL APPROACH TO PREVENTIVE MEDICINE*

PERRIN H. LONG
M.D. Ann Arbor, F.R.C.P.
From the Department of Preventive Medicine, Johns Hopkins University School of Medicine

LAST spring, when I read the report on the U.S.A. medical curriculum, prepared by the Association of Interns and Medical Students from the returns of a widely disseminated questionnaire, I was amazed to find that instruction in public health (preventive medicine) stood third in the list of subjects which, in the opinion of the respondents, should be de-emphasised. This surprised me, not only because it ran counter to current social, economic, legislative, and educational trends, but also because it was derived from that segment of our profession which ordinarily is advanced in its social and educational consciousness.

This report should not be lightly dismissed. We cannot ignore it by remarking that the sample was probably inadequate, that it reflects the intellectual immaturity of the students and the undesirable educational features of the accelerated programme, or that it is symptomatic of either the disorganisation or the over-organisation which has existed in the teaching of preventive medicine during the past few years. Rather, it seems to me, this report must make us all stop and think about the general approach we are making to preventive medicine, the content and placing of our courses, and the philosophies with which we are attempting to inculcate our students. We should approach the subject with a spirit of inquiry and in a mood for self-criticism. Let us do this individually and collectively since the philosophies and methods of instruction in preventive medicine—because of the lack of a clear definition of the subject (which is so well shown by our various titles), and because of the nature of our individual training—vary more in medical schools in U.S.A. than do those of practically any other subjects included in the medical curriculum.

WHAT PREVENTIVE MEDICINE IS

A review of the current philosophies and trends in the teaching and practice of preventive medicine is necessary for an appraisement of the various methods of instruction used in presenting this subject to the students. As Ryle (1943) has so ably pointed out, "three great historical epochs exist in preventive medicine." During the first epoch the initial approaches to sanitation, proper working conditions, adequate housing, &c., were made, and empirical methods for the control of infectious diseases, such as typhus, yellow fever, smallpox, typhoid fever, and cholera, were put into effect. These measures were continued and extended in the second epoch under the influence of the development of microbiology and sanitary science to a point which, at least in certain parts of the world, has brought many infectious diseases under control and reduced their ravages to a minimum. At present we are living in the end of the second and in the beginning of a third epoch, in which prominence will be given to the prevention of non-infective diseases, the rehabilitation of the sick, and the mitigation of chronic or degenerative disease, and physicians, if they wish to survive either professionally or economically, will become increasingly conscious of the necessity for maintaining a primary interest in the promotion of health rather than the alleviation of illness.

Sir George Newman (1932) conceived of medicine as having three aims: the cure of disease (curative medicine); the prevention of disease and the modification of the course of established disease (preventive medicine): and the conservation of the natural defences of individuals and communities through favourable environmental and other factors to produce a way of life favourable to health (conservative medicine, constructive medicine, or hygiene). In his opinion, when efforts in the prevention or the modification of disease are directed towards the protection of the community and the improvement of its external environment, they fall within the realm of public health.

Leathers (1938) defined the subject as follows: "Preventive medicine constitutes a part of clinical medicine, obstetrics, pædiatrics, and psychiatry, and even much of surgery. Its purpose is to avert those disorders for which there are specific preventive measures, to detect early by accurate and thorough methods of diagnosis the beginnings of illness for which remedial therapy may be applied. Its objective is to aid in the solution of social, economic, and welfare problems of the community in relation to disease. It involves the uses of a specific technique in dealing with the public. The application of the principles of preventive medicine through organised administrative procedure in relation to local, state, or national needs constitutes public health."

Perkins (1942) has written: "Preventive medicine is not a specialty. . . . It is not public health. . . . It is not hygiene or sanitation. It is a philosophy and a science having practical application in every phase of clinical medicine. . . . Preventive medicine must maintain contact with clinical medicine at all points" and "should be a clinical branch."

Smillie (1943) states that preventive medicine "comprises those activities that are the direct responsibility of the individual in the prevention of disease, and in the promotion of the health of himself and his family. . . . The person who is most responsible (for these activities) is the private practitioner of medicine, who serves as health adviser to each family in the community." Public health, on the contrary, "encompasses those activities that are undertaken for the prevention of disease and the promotion of health that are a community-wide responsibility." They are not carried out by a practitioner of medicine.

Barnes (1943) and Anderson (1943) believe that public health is a specialty which should not be taught as such in medical schools, because it is beyond the needs and scope of the average medical student. Both emphasise the epidemiological approach to the study of disease, and Anderson feels there is a definite need for coördinating the instruction regarding communicable diseases (epidemiology) with the clinical instruction in these diseases.

Hitchens (1943) has emphasised the importance of instruction in environmental sanitation to provide the student with the proper appreciation for public health.

Wampler (1943) feels that, as "the most important function of the physician is to keep his patients well," and as this concept is the keystone to the intelligent practice of industrial medicine, an approach to preventive medicine through industrial medicine offers much hope in teaching.

Grant (1943) has concluded, after almost twenty-five years' experience, that environmental case-studies offer a valuable approach in the teaching of preventive medicine.

Probably Ryle (1943) has summed up the implications of the latest British concepts in this broad field when he says that social medicine is not just another name for preventive medicine, and that social medicine and socialised (State) medicine are not synonymous. It is his belief that social medicine is a direct development in and expansion from clinical medicine, and that it concerns the group as well as the individuals comprising the group in regard to sickness in the family and in the community:

> "It embodies the idea of medicine applied in the service of man as *socius*, as fellow or comrade, with a view to a better understanding and more durable assistance of all of his main and contributory troubles which are inimical to active health, and not merely to removing or alleviating present pathology. It also embodies the idea of medicine applied in the service of *societas*, or the community of men, with a view towards lowering the incidence of all preventable disease and raising the general level of human fitness."

In concluding this review of concepts of the content and teaching of preventive medicine, I wish to dwell at some length on the views set forth by Smith and Evans (1944):

> "Preventive medicine might be logically defined as all medicine that seeks to alter the course of disease or to better

---

* Read before the Conference of Professors of Preventive Medicine on Sept. 30, 1946.

was based on the following observations. Nine out of ten of the graduates of the Johns Hopkins University School of Medicine enter into the practice of medicine or surgery or the specialties. As has been pointed out by Smillie (1943), the mission of undergraduate instruction in preventive medicine is not "to prepare students to become grade-B health officers" but rather "to meet their obligations as private practitioners of medicine." If most of one's students become practitioners it seems logical to attempt by the clinical approach to inculcate the philosophy, besides assisting other clinical departments to provide a knowledge of the practical aspects, of the prevention or modification of disease, especially the promotion of health.

A further consideration of teaching in preventive medicine brought me to the problem of the present curricula in our medical schools. From the day a student enters medical school practically his total outlook is focused on diagnosis and treatment. Anatomy, bacteriology, biochemistry, physiology, pharmacology, and pathology are more or less exciting and at times completely isolated milestones along the road to the clinic. All of us can remember the excitement and the intense satisfaction which pervaded us when at last we had worked up our first "case." We had a feeling that we had arrived.

The philosophy of clinical teaching at the bedside, so laudable in its inception, because it took medical students from lecture halls into hospital wards, has become restricted in its concept. The interest of the medical student is focused on the sick man recumbent in a hospital bed. But slight attention is paid to what brought the patient to the hospital, and when, owing to his own natural resistance or to the administration of one of the few "specifics" in modern medicine, he becomes ambulatory, interest in him rapidly wanes. Little consideration is given to his problems of convalescence or to his physical and mental rehabilitation.

Medicine today has become more specialised and more technical, with the result that its students are required to assimilate vast quantities of precise and intricate information. This is the result of the remarkable progress which has characterised medicine during the last quarter of a century. With the continuous increase in the definition of our knowledge, medicine and the teaching of medicine have tended to be compartmentalised in our medical schools. Disease has become a jigsaw puzzle whose integral parts are scarcely ever put together by one person to obtain the whole. Specialists and corps of technicians are required for its solution. Research is "directed and coördinated," because it is thought that many fields have become too broad for the individual endeavour. Is it any wonder, then, that the instructor and the student, staggering together under the impact of the increasing and continuous flow of new medical knowledge, have little time, as Ryle (1943) has said, for "the old ætiological interest and humanism of our fathers"? It is beginning to appear that the more they learn the less they understand. The eminent specialist, the great worker in research, and the expert and dexterous surgeon have become the gods of the students, and specialisation their goal. It is in such a milieu that preventive medicine must compete for the students' attention and contemplation, and it seemed to me that as a subject it would fail in its aims unless presented upon an equal and integrated basis in all of the school years by instructors who were well grounded in the various fields of general medicine, besides being imbued with the philosophy of preventive medicine.

Health economics and the social, environmental, and religious aspects of illness are directly concerned with, and stem from, the patient or groups of patients. It is therefore obvious that, for a proper understanding of the economy of health and the cost of illness, and for the proper appreciation of the rôle played by social and environmental factors in disease, a broad knowledge of clinical medicine is needed. In the approach to teaching in these fields, it has therefore seemed to me that the clinical approach is logical, because only through such an avenue can a proper appreciation of the many problems be achieved. I do not mean to infer by this statement that use should not be made, in teaching preventive medicine, of the material which can best be collected, analysed, and presented by trained non-medical observers; nor do I feel that the contributions made to medicine by the newer sociology should be neglected. The assistance of all branches related to medicine should be enlisted and the experts in the various fields employed in teaching programmes—but always under the supervision and guidance of one who, through training and experience in the natural history of disease, can leaven the presentation with the clinical aspects of the problem under discussion.

Finally, it is my belief that, from the point of view of pedagogy in preventive medicine, the clinical approach is preferable. One of the dangers in all types of education is for the instructor to present material which is either beyond the intellectual comprehension of his auditors or sharply limited in its subject interest by the instructor's own training and interests. The great teacher is easily understood. Instructors who have had a broad training in general medicine, with the daily multiple contacts with patients which such a training requires, generally have the ability to explain things medical in relatively simple terms. If this simplicity can be coupled with a sympathetic enthusiasm (but not emotional instability) and an ability to present the facts logically, the unrelated subjects which often make up the content of preventive medicine can be brought into a perspective which is proper in its relation to the remainder of the medical curriculum.

TEACHING

When preventive medicine stems from the clinical approach, biostatistics becomes "quantitative methods in medicine," with instruction in vital statistics reduced to the necessary minimum and the accent placed on the mathematical approach to diagnosis and prognosis, the quantitative testing of alleged "data," and the development of a logical rather than an impressionistic approach to the problems of illness. Patients can and should be used in this teaching, and the terminology of biostatistics, at present tending to become a jargon, can be reduced to English.

Epidemiology, shorn of much of its methodology and technology, becomes the natural history of disease when approached from clinical medicine. The discussion of the origin, spread, and course of disease, of those natural or artificial factors which tend to alter its spread, of its patterns and of the effect of political, social, religious, economic, and environmental factors which affect such patterns, is a basic requirement if a proper philosophy of preventive medicine is to be inculcated in the students. Indeed, this course, if not restricted and narrowly limited by the thinking of the first and second epochs of preventive medicine, could be termed the foundation course of general medicine. It is obvious that teaching, dealing with the social, economic, and environmental aspects of illness, must stem from the patient and his record. The economy of health and problems of medical care of the ill originate from the patient and lose much of their reality when presented in the abstract from masses of cold and often lifeless statistics. Their interpretation and elucidation gain much from clinical understanding. The same is also true in so far as the teaching in the communal aspects of medicine is concerned. Who can really understand or appreciate deeply the problems of the group unless he has a thorough knowledge of the problems and reactions of the individual?

lupus cured with the enormous dosage of 1000 g. of cod-liver oil daily. Evidently this treatment was too heroic, for the dose was reduced by his successors to something more palatable but ineffective, and Emery was forgotten. The next advance in lupus therapy was the introduction of heliotherapy and of concentrated ultraviolet light as local treatment by Finsen in 1897. In 1927 Sequeira and O'Donovan showed that the addition of daily general artificial light baths enhanced the effect of local light.

The next stage was the isolation of vitamin D from cod-liver oil and the preparation of vitamin D_2 by exposing ergosterol to ultraviolet light, culminating with the isolation of pure calciferol in 1931. Credit for this goes to many biochemists, starting with Mellanby in 1919. At first it was feared to give calciferol in massive doses because of possible toxic effects, such as had occurred with 'Vigantol' (*Lancet* 1946). It was used in small experimental doses in rickets, until in 1936 a child being treated for spasmophilia (Harnapp 1936) inadvertently swallowed a dose of 15 mg. (600,000 units). Not only did the child survive but the rickets was rapidly cured, and the way was open for Charpy to start treatment of lupus by this means in 1941.

The claim of a cure by Charpy (1943) was supported during the next two years by many French dermatologists. These were listed by Bureau (1946) in order as follows: Gougerot and Gaullier, Clement Simon, Touraine, Degos, Michel and Pellerat, Thiers, Huriez, Garric, and Bureau and Barrière. The earlier reports claimed 100% cure; but, later, less success was claimed. A cure in 70–100% of cases is now claimed in France, according to a referendum recently conducted among the French dermatologists by Charpy (1946). There was, however, one much less favourable reply from Meyer (1946), whose experience, much larger than that of the others, is mentioned below.

As part of the treatment Charpy emphasises that the addition of calcium is necessary, though in 1944 he favoured a fractionated or more intensive method of giving the calciferol. Also, in the Charpy method, local treatment of residual lesions is used occasionally.

Bureau and Barrière (1945) reported one case cured without the addition of calcium. Meanwhile, in England, Dowling and Prosser Thomas (1945) had been treating lupus with massive doses of calciferol independently for two years, also without calcium and usually with less associated local treatment: their results were equally good.

Histological cure was reported by Charpy (1945), Peyrie (1945), and Bureau (1946), in one case with negative serial sections of the residual scar and in another with negative biopsy of the scar and negative result from guineapig inoculation. Vachon (1944), however, found histological evidence of lupus still present in a series of 4 cases treated with calciferol without local treatment. Vachon and Feroldi (1945) did not find histological cure in any of 7 cases treated by the Charpy method, but the biopsies may have been made too soon (Charpy 1946). Vachon and Feroldi also found no calcium deposits in any of their sections. This finding contrasted sharply with those of Levaditi and Li Yuan Po (1930) in experimental tuberculosis in rabbits treated with irradiated ergosterol (two years before pure calciferol became available) where completely calcified follicles in tuberculous orchitic tissue were found.

Clinical reports on the effects of calciferol in other forms of systemic and cutaneous tuberculosis have been made by Bell (1946), Lapierre et al. (1946), Thiers et al. (1946), Wallace (1946), Macrae (1946), Jones (1946), and Wilkinson (1946). A complete bibliography of the preceding references is given in *Ann. Derm. Syph., Paris*, for May–June, 1946.

TABLE I—RESULTS OF TREATMENT OF LUPUS WITH CALCIFEROL

Months under observation	No. of cases	No. in which D_2 alone had no apparent effect	Associated general light baths	Associated local treatment	Worse	Relapsed	No change	Improved but not healed	Healed	Healed lupus cases; D_2 substituted for general light without relapsing	% of active cases either improved or healed	% healed
11–12	12	4	0	11	0	0	1	9	2	—	*92*	*17*
10–11	30	6	3	15	2	0	1	17	9	1	*90*	*31*
9–10	30	6	4	20	0	2	4	15	9	—	*80*	*30*
8–9	9	1	1	3	0	0	0	6	3	—	*100*	*33*
7–8	19	3	3	11	0	0	3	10	6	—	*84*	*32*
6–7	12	4	1	6	0	2	1	6	1	2	*70*	*10*
5–6	12	5	1	8	0	0	5	6	1	—	*58*	*8*
4–5	26	14	1	13	1	0	12	6	5	2	*46*	*21*
Totals	150	43	14	87	3	4	27	75	36	5	*77*	*25*

Toxic effects, as distinct from symptoms of intolerance, have been reported from the use of calciferol in lupus dosage by Merklen (1945), Bureau and Gougerot (1945), Bureau (1945), and, in a case of hypoparathyroidism, by Eaton (1946).

Findings in serial estimations of the blood-calcium level have been reported by Dowling and Prosser Thomas (1946) and Meyer et al. (1946). Findings in serial estimations of the blood-sedimentation rate have been published by Vachon (1944), Meyer et al. (1946), and Feeny (1946).

RESULTS

None of the 150 cases in the present series has been under observation for less than four months, as it was thought that a shorter period would not allow sufficient time for continued improvement or relapses to be noted. The dose of calciferol used was 100,000 units daily, and this was increased to 150,000 units if it was thought that the patient could tolerate the larger dose or was not improving satisfactorily on the smaller one. Occasionally the dose was temporarily reduced to 50,000 units daily, or the initial dose was 50,000 units, and this was raised, if well tolerated, to the larger doses.

Table I shows the progress of the cases in month groups, the degree of success or failure obtained, and the extent to which the therapy formerly in use was retained. These results should be compared with those of Meyer et al. (1946), who observed a similar number of cases for two years (1944–45). Of their 148 cases, 31 (21%) were cured and remained so, 25 relapsed after apparent cure, 72 were improved but not cured, and the remaining 20 (13%) were failures. The degree of success or failure obtained is very similar in these two investigations, the only large-scale ones hitherto reported. The smaller number of relapses in the London Hospital group may possibly be explained by the conservatism in the use, without histological confirmation, of the word "cure," which has long been customary at this lupus clinic. For example, O'Donovan (1944) indicates the large experience necessary to give a positive clinical opinion on this point, and Burrows (1938) draws attention to the periods of quiescence which alternate with periods of spread in lupus. A striking example of what can happen in a "sound" lupus scar occurred while this investigation was in progress:

A middle-aged woman, whose lupus had developed in childhood and had been "cured" or "sound" for a considerable time, attended for periodic examination. It was noted that since her previous attendance she had developed a granulomatous looking nodule in the middle of her solitary lupus scar. Biopsy of the complete nodule and repeated blood examinations showed that this was a nodule of lymphatic

It might be asked at this point how the type of teaching just described can be put into effect, and how preventive medicine can be established as a clinical subject. To begin with, *departments of preventive medicine should* be staffed with members who by training will not only be acceptable for appointment on clinical staffs of teaching hospitals but also can hold their own in clinical and research fields. Secondly, teaching in preventive medicine should be *integrated with instruction in all* departments of a medical school. Every effort should be made to have the various phases of its philosophy presented to students, interns, and staff in discussions of all clinical problems. Other departments should be encouraged to utilise the student's knowledge of quantitative methods in medicine to further the development of a logical, rather than an impressionistic, type of thinking in medicine. *Too often in clinical instruction the* quantitative approach to the preparation or analysis of data is ignored or even disparaged by those who are unfamiliar with the proper rôle of statistical methods in medicine. Thirdly, representation should be sought on all professional boards of teaching hospitals for members of the department of preventive medicine to provide the necessary leaven of humanism. Fourthly, separate clinical facilities are unnecessary if the staff of the department has been properly integrated with other staffs of the hospital. In those university medical centres in which the supervision of the health and the medical care of students, nurses, interns, employees, &c., is a responsibility of the department of preventive medicine the infirmary for the minor sick should be under its direct charge. A medical-centre health clinic provides a direct approach for instruction in and the practice of preventive medicine. Its value cannot be overestimated.

TRENDS

I have stated previously that I would not attempt to define preventive medicine, because I felt that it was not a science but rather a philosophy of the teaching and practice of medicine. However, I do believe that it is possible to outline certain of the important trends in this subject and to formulate its aims. I cannot agree wholly with Ryle when he says that social medicine is "a logical development *from* [italics mine] and a direct expansion of clinical medicine." If he had only said "in" instead of "from" clinical medicine, we would be in complete agreement. "Preventive medicine," "social medicine," "eubiotic medicine," or whatever one desires to call that branch of medical teaching and practice in which we are interested, can no more be separated from general clinical medicine than can the stethoscope from the clinician, or the scalpel from the surgeon. All attempts at such a separation are artificial in their conception and create a confusion rather than a clarity of purpose and mission. The fruits of our best efforts towards the promotion of health, the prevention or alteration of the ravages and effects of disease, the better understanding of the economic, social, and environmental factors in health and disease, indeed the whole of our philosophy in medicine, will be reflected primarily in the attitudes which we create in our colleagues and students.

We are living in an age which has produced and will continue to produce great changes in the social and scientific structure of our profession. Today, while the fruits of medical progress are being enjoyed in some parts of the world, in other parts medical care has been reduced to a minimum. It is a time of simultaneous sunrise and twilight in medicine. We have entered a period in which more than ever before it is the duty of our profession to maintain its historical perspective. We must not fear bold experimentation in the promotion of health, but at the same time we must not confuse hypothesis or theory with the truth. We must be prepared to present the facts which will permit an informed electorate through its representatives to exercise its proper opinion in respect to medical care. It is a time in which logical and [illegible] thinking and intellectual honesty concerning problems medical care should displace superficial emotionalism, cant, or *laisser-faire* reactionism. We must free ourselves from the traditions created by the spirit of the guild in a time when disease was the normal state of mankind, and lead the way in perpetuating health rather than sedulously occupying ourselves with the problems of disease. It is the time when the practice of preventive medicine should become the preoccupation of every physician and surgeon.

TOWARDS SELF-EXTINCTION

Despite the broad advances which have been made in most fields of medicine during the last century, there is still ample time, both in the teaching and practice of medicine and its specialties, to proclaim and practise those humanistic principles which have been lost sight of in the process of learning more and understanding less. It should be our purpose by precept and by example to advance in the teaching and practice of general medicine those principles in the promotion and protection of human health and welfare which have always pertained and still pertain to the broad field of medicine and are not bound down by narrow specialisations. We exist because others have either forgotten or neglected certain basic precepts of medicine.

With this philosophy in mind, what should be the aim of a department of preventive medicine? It should be one of gradual self-extinction in every medical school. Its course should be carefully charted, and its success should only be considered complete when, owing to its efforts and its endeavours, the level of the instruction in and practice of humanistic medicine has been raised to such a point in all departments in a medical school that the continued presence of a department of preventive medicine is unnecessary.

A YEAR'S experience (1945–46) in the treatment of lupus vulgaris at the London Hospital with massive doses of calciferol (vitamin D_2) is recorded here. At the same time its therapeutic effect in pulmonary tuberculosis was investigated at the Kettlewell Hospital, and a report of the findings is included.

Lupus Vulgaris

(P. J. F.)

The story of how calciferol came to be used at Dijon in the treatment of lupus is told by Charpy (1946), the original user. It had been known for a long time that the administration of cod-liver oil was beneficial in tuberculosis, and Emery in 1848 recorded 74 cases of lupus cured with the enormous dosage of 1000 g. of cod-liver oil daily. Evidently this treatment was too heroic, for the dose was reduced by his successors to something more palatable but ineffective, and Emery was forgotten. The next advance in lupus therapy was the introduction of heliotherapy and of concentrated ultraviolet light as local treatment by Finsen in 1897. In 1927 Sequeira and O'Donovan showed that the addition of daily general artificial light baths enhanced the effect of local light.

The next stage was the isolation of vitamin D from cod-liver oil and the preparation of vitamin D_2 by exposing ergosterol to ultraviolet light, culminating with the isolation of pure calciferol in 1931. Credit for this goes to many biochemists, starting with Mellanby in 1919. At first it was feared to give calciferol in massive doses because of possible toxic effects, such as had occurred with 'Vigantol' (*Lancet* 1946). It was used in small experimental doses in rickets, until in 1936 a child being treated for spasmophilia (Harnapp 1936) inadvertently swallowed a dose of 15 mg. (600,000 units). Not only did the child survive but the rickets was rapidly cured, and the way was open for Charpy to start treatment of lupus by this means in 1941.

The claim of a cure by Charpy (1943) was supported during the next two years by many French dermatologists. These were listed by Bureau (1946) in order as follows: Gougerot and Gaullier, Clement Simon, Touraine, Degos, Michel and Pellerat, Thiers, Huriez, Garric, and Bureau and Barrière. The earlier reports claimed 100% cure; but, later, less success was claimed. A cure in 70–100% of cases is now claimed in France, according to a referendum recently conducted among the French dermatologists by Charpy (1946). There was, however, one much less favourable reply from Meyer (1946), whose experience, much larger than that of the others, is mentioned below.

As part of the treatment Charpy emphasises that the addition of calcium is necessary, though in 1944 he favoured a fractionated or more intensive method of giving the calciferol. Also, in the Charpy method, local treatment of residual lesions is used occasionally.

Bureau and Barrière (1945) reported one case cured without the addition of calcium. Meanwhile, in England, Dowling and Prosser Thomas (1945) had been treating lupus with massive doses of calciferol independently for two years, also without calcium and usually with less associated local treatment: their results were equally good.

Histological cure was reported by Charpy (1945), Peyrie (1945), and Bureau (1946), in one case with negative serial sections of the residual scar and in another with negative biopsy of the scar and negative result from guineapig inoculation. Vachon (1944), however, found histological evidence of lupus still present in a series of 4 cases treated with calciferol without local treatment. Vachon and Feroldi (1945) did not find histological cure in any of 7 cases treated by the Charpy method, but the biopsies may have been made too soon (Charpy 1946). Vachon and Feroldi also found no calcium deposits in any of their sections. This finding contrasted sharply with those of Levaditi and Li Yuan Po (1930) in experimental tuberculosis in rabbits treated with irradiated ergosterol (two years before pure calciferol became available) where completely calcified follicles in tuberculous orchitic tissue were found.

Clinical reports on the effects of calciferol in other forms of systemic and cutaneous tuberculosis have been made by Bell (1946), Lapierre et al. (1946), Thiers et al. (1946), Wallace (1946), Macrae (1946), Jones (1946), and Wilkinson (1946). A complete bibliography of the preceding references is given in *Ann. Derm. Syph., Paris*, for May–June, 1946.

Toxic effects, as distinct from symptoms of intolerance, have been reported from the use of calciferol in lupus dosage by Merklen (1945), Bureau and Gougerot (1945), Bureau (1945), and, in a case of hypoparathyroidism, by Eaton (1946).

Findings in serial estimations of the blood-calcium level have been reported by Dowling and Prosser Thomas (1946) and Meyer et al. (1946). Findings in serial estimations of the blood-sedimentation rate have been published by Vachon (1944), Meyer et al. (1946), and Feeny (1946).

RESULTS

None of the 150 cases in the present series has been under observation for less than four months, as it was thought that a shorter period would not allow sufficient time for continued improvement or relapses to be noted. The dose of calciferol used was 100,000 units daily, and this was increased to 150,000 units if it was thought that the patient could tolerate the larger dose or was not improving satisfactorily on the smaller one. Occasionally the dose was temporarily reduced to 50,000 units daily, or the initial dose was 50,000 units, and this was raised, if well tolerated, to the larger doses.

Table I shows the progress of the cases in month groups; the degree of success or failure obtained, and the extent to which the therapy formerly in use was retained. These results should be compared with those of Meyer et al. (1946), who observed a similar number of cases for two years (1944–45). Of their 148 cases, 31 (21%) were cured and remained so, 25 relapsed after apparent cure, 72 were improved but not cured, and the remaining 20 (13%) were failures. The degree of success or failure obtained is very similar in these two investigations, the only large-scale ones hitherto reported. The smaller number of relapses in the London Hospital group may possibly be explained by the conservatism in the use, without histological confirmation, of the word "cure," which has long been customary at this lupus clinic. For example, O'Donovan (1944) indicates the large experience necessary to give a positive clinical *opinion* on this point, and Burrows (1938) draws attention to the periods of quiescence which alternate with periods of spread in lupus. A striking example of what can happen in a "sound" lupus scar occurred while this investigation was in progress:

A middle-aged woman, whose lupus had developed in childhood and had been "cured" or "sound" for a considerable time, attended for periodic examination. It was noted that since her previous attendance she had developed a granulomatous looking nodule in the middle of her solitary lupus scar. Biopsy of the complete nodule and repeated blood examinations showed that this was a nodule of lymphatic

* = Apparent cure (6 out of 22 cases).

leukæmia. There were no other signs or symptoms, and this patient still does not complain of anything several months later.

Before the advent of calciferol therapy there was 20% failure in treating lupus with general and Finsen light (Sequeira and O'Donovan 1927, Lomholt 1934). With the addition of calciferol there is little or no alteration in this percentage. The great advance has been the time saved (half to two-thirds) and the greater ease in treatment. The third and last two columns of table I indicate that treatment is increasingly efficacious for nine months. The third column shows that, though in 43 cases (29% of the 145 active cases) there was no apparent effect from the use of calciferol alone, nearly a third of these were in the group observed for only four to five months.

The response to treatment in the 14 cases which also had general light baths was the same as that in the 130 cases which did not have general light, and it is impossible to say whether any improvement was obtained more rapidly. But in the vast majority of cases the patient was now independent of general light, and this is a great advantage. Most patients have general light treatment in their home districts, but it has always been difficult for many of them to get it more than two or three times a week. There were, however, two cases in the present series which relapsed when calciferol was substituted for general light baths. These patients had always relapsed in the past whenever general light had been discontinued. Charpy (1944) suggests that less success is obtained when there is liver insufficiency.

Figures do not do justice to the outstanding improvement noted in many cases or to the consequent moral uplift of a class of "untouchables."

Illustrative Cases.—In 6 cases long-standing mucosal lesions were healed within several weeks, but 1 of them relapsed while still on calciferol. The accompanying lesions on the skin improved much more slowly.

One case had relief in a fortnight from pruritus ani due to perianal lupus. Previously all treatment for two years had failed to relieve this symptom.

Another case, where no reactions could be obtained with Finsen light, was apparently cured with calciferol.

The incidence of cases with signs of old pu tuberculosis was 1 in 15, and the incidence of cases the development of lupus followed tuberculous in childhood was 1 in 11. Only 1 case now had pulmonary tuberculosis. While awaiting admission another hospital this patient was given 100,000 units calciferol daily for six weeks. On admission there also signs of renal tuberculosis. It was learned this patient then preferred to go home, where she fifteen weeks after the administration of calciferol been discontinued.

In 3 women who became pregnant the lupus improved: 1 of them, who had already improved before was given, became apparently sound after two months; another developed acute iritis for the first time in the seventh month of pregnancy. Wilkinson (1946) the case of a woman, not on calciferol, in whom the cleared when she became pregnant.

A case in which moderate hyperthyroidism had been present for twenty years did not improve an observed period of twenty weeks.

An unusual case was in a man, aged 19, with lupus of the chin. On calciferol alone there was rapid though incomplete healing for two months, but with keloid scars. Finsen light was then added to the therapy, with the formation of much pigmentation locally, but there was no further improvement during the next four months. There had been no history of other keloidal formation in this case.

Cases Previously Treated with X rays, Radium, or Grenz rays.—In the past, for those who had access to Finsen light, it had always been the aim to complete local treatment as soon as possible, lest old fibrous tissue should interfere with the absorption of the ultra violet rays. X-ray treatment, which often was excessive, caused a similar difficulty, besides causing an added carcinoma in some instances. The clinical effect of calciferol therapy on all the cases in this survey who had ever been treated with X rays, radium, or Grenz rays is shown in table II.

Many of these patients had been subjected to prolonged X-ray treatment in various clinics very many years ago before the dangers of this procedure had been appreciated. But the results summarised in this table do not greatly differ from those in table I. One would like to have a better understanding of the mode of action of calciferol on lupus, and an opinion, based on histopathological examination of many serial biopsies, before reaching any conclusion about these findings.

Cases of Lupus Carcinoma and Premalignancy.—In 3 cases there was lupus carcinoma, and in 9 others an active lupus with healed or potentially malignant accompaniments. The clinical effect of calciferol therapy in these cases is shown in table III. Of the 7 patients who had at any time developed lupus carcinoma 3 had previously been given X-ray treatment.

In this series calciferol had no clinical effect on established lupus carcinoma, but suspected premalignancy was dispersed in at least 3 cases (marked with an asterisk in table III). The development of granuloma annulare in one case after thirty weeks' calciferol therapy is noteworthy

OTHER OBSERVATIONS

Intolerance.—Symptoms of intolerance were present in 35 cases (23%) and took the form of nausea and anorexia with, very rarely, vomiting. The drug was dispensed either in a tablet or in a mucilage. Dowling and Prosser Thomas (1945) noted 21% intolerance in 38 cases, but Charpy (1946) had not observed this complication in any of his cases—probably because the vehicle was alcoholic.

The addition of vitamin B_1 (1 mg. t.i.d.) or yeast was without effect on tolerance in 24 out of 25 cases. In the remaining patient nausea, which had been present for three weeks, was relieved.

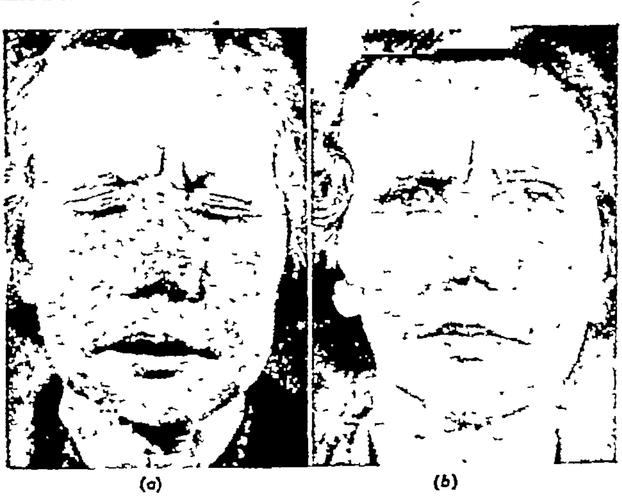
Addition of Calcium.—Calcium phosphate gr. 20 t.d.s.p.c. was given in 42 cases, and in 10 of them at the start of calciferol treatment. The clinical response in these 42 cases during a period of observation of 17–27 weeks was: 7 cases apparently healed; 21 improved but not healed; 11 unchanged; 2 relapsed; and 1 got worse. In 3 of these cases calciferol was better tolerated when calcium phosphate was added. One patient complained of flatulence, one of diarrhœa, one of constipation, one could take only half the dose of calcium, and another could take none.

It is now well established that the addition of calcium is not essential. According to McLaren (1946) it is dangerous to give one of the usually recommended preparations, calcium gluconate, by intramuscular injection. The amount of calcium given daily in the above cases was double the normal requirement, and there was no additional clinical benefit. Holmes (1945), who extensively reviews the literature and quotes many authors, states that seldom in his lifetime does the average person utilise even half the amount of calcium he consumes. But in France additional calcium is regarded as necessary, and one has only to study the statistics of Debré (1945) to see why this conception arose. These statistics concern food conditions in France during and after the German occupation, and it is certain that from 1941 until 1945 lupus patients in France, at least in the towns, were suffering from lack of calcium, even if they did get extra milk.

TABLE III—RESULTS OF CALCIFEROL THERAPY IN MALIGNANT OR PREMALIGNANT CASES

Previous radiation therapy	Weeks under observation	Weeks before signs appeared	Description	Clinical effect of calciferol at end of observation period
None	50	18	Lupus carcinoma	Lupus and carcinoma both healed 20 weeks after treatment of carcinoma with radon seeds
”	47	Present initially	Lupus carcinoma healed for 9 years; active lupus	Lupus improved +—
X rays	46	36	Cutaneous horn in lupus area	Lupus improved +; cutaneous horn unaffected
*Grenz rays	46	Present initially	Ulcerated lupus	Lupus improved +; potential malignancy dispersed
None	47	13	Healed lupus carcinoma; lupus still active	Improved +
*X rays	22	22	Septic erosion at site of healed lupus carcinoma	Improved ++, no development of malignancy
”	28	Present initially	Lupus in X-ray skin with healed lupus carcinoma	None
None	40	29	Papilloma in lupus area	Lupus improved ++, no sign of malignancy in papilloma
”	39	34	Recurrence of lupus carcinoma	None; after 15 weeks malignant area needed treatment with radon
*”	39	Present initially	Keratoses in lupus area	Improved ++ with reduction in size of keratoses
X rays	44	Present initially	Severe X-ray atrophy with active lupus	Lupus improved +; no development of malignancy; after 30 weeks granuloma annulare developed
”	42	25	3rd recurrence of lupus carcinoma	None on lupus; this recurrence more malignant; regional glands enlarged after 17 weeks

* Suspected premalignancy dispersed in these cases.



(a) (b)

Lupus vulgaris treated with calciferol: (a) Jan. 10, 1946, at start of treatment; (b) 14 days later.

Toxicity.—Apart from the frequent minor features of mental depression, giddiness, and abnormal tiredness, there were 6 cases of frequency of micturition, 2 of them with albuminuria, in the series. In each case the frequency and albuminuria ceased within two or three weeks when the calciferol was discontinued. There were also 2 cases of arterial calcification, the ages of the patients being 73 and 77. One of these, after six and a half months, showed calcification of the abdominal aorta and a single calculus in one kidney; the other, after four months, had calcification of the arteries of the pelvis. Calciferol was suspended for two weeks and four months respectively. In each case the lupus continued to improve on resumption of the drug and the patient felt no ill effects. The dose on resumption was reduced to 50,000 units daily.

Dosage.—The successful further use, after a rest interval, of a smaller dose of calciferol in the 2 cases where arterial calcification had occurred should be correlated with the parallel experience of Eaton (1946), whose case of hypoparathyroidism, showing peripheral arterial calcification after sixty-four days on 90,000–200,000 units of vitamin D_2 daily, had attained complete freedom from tetanic attacks of fifteen years' duration. Calciferol was then discontinued, and the attacks recurred. A smaller dose (max. 30,000 units daily) was then given for a year and though calcification increased slightly the patient was almost free of tetany. Meyer et al. (1946) thought that the size of the dose, so long as it was massive, did not matter in their 148 cases. Krestin (1945), who used massive doses in treating 83 infants with rickets, states that pure calciferol will not produce toxic signs until over 2,000,000 units has been given, but he found that his smaller massive dose (300,000 units) was less efficacious than his larger one (600,000 units). Another relevant finding is that of Heymann (1937), that storage of large doses takes place in the liver and other organs for so long as twelve weeks. The optimum dose in lupus has still to be decided, and there seems to be a large factor of personal idiosyncrasy to calciferol. Compare the spectacular response in a fortnight to a dose of 50,000 units daily (see figure) with those cases in table I where treatment with larger doses for many months was without clinical effect.

LABORATORY FINDINGS

Sedimentation-rate.—Vachon (1944) reported that with calciferol therapy the erythrocyte-sedimentation rate (E.S.R.), always raised in lupus, was reduced by 10–15% without however returning to normal. Meyer et al. (1946) maintain that the rate does not vary with the therapeutic results; when high, it remains high in spite of cure; and, when low, it is not modified accordingly. In general, they say, an initial high rate leads to hope of greater efficacy in treatment.

My impression, mentioned in a preliminary report on 32 cases (Feeny 1946), that this test is of no value in judging the progress of lupus treated with calciferol, was confirmed in a larger number of cases, as the following observations show.

The E.S.R. was recorded in 55 patients with active lupus to whom no calciferol had been given. Wintrobe's technique was used, the result being corrected for anæmia by determination of the hæmatocrit reading. In 80% of these cases the readings were within normal limits. Serial estimations of the E.S.R. were then made in 72 active cases during the first seven months of treatment with calciferol. In 30 of these cases (23 of which were improving clinically, 6 showing no change, and 1 getting worse) the readings remained within normal limits. In 15 cases readings above normal remained so, while clinically 13 of them were improving and 2 showing no change. In 20 cases readings rose to above normal, while clinically 14 of them were improving, 5 showing no change, and 1 deteriorating. The 7 remaining cases—i.e., those in which the readings returned to normal—all improved clinically.

The plasma fibrinogen was recorded in 12 cases, because an increased E.S.R. is found when the fibrinogen is raised. The method used was that of Cullen and Van Slyke with micro-Kjeldhal determination of the fibrin precipitate (Peters and Van Slyke 1932). The readings ranged from 280 to 418 mg. per 100 c.cm. and were therefore within the range of normal—i.e., 250–450 mg. per 100 c.cm. (Panton and Marrack 1945).

It may therefore be said that in lupus, a chronic and localised form of tuberculosis, the E.S.R. is usually normal; the exhibition of calciferol often causes an increase in the E.S.R.; and the E.S.R. is of no use as a test of the efficacy of lupus therapy.

Lymphocyte-counts.—The possibility that serial lymphocyte-counts might be of use as an index of progress in lupus therapy was also explored. Of 53 cases to which calciferol had not been given, the readings were within normal limits in 14, above normal in 29, and below normal in the other 10 cases. Serial estimations were made in 73 cases treated for four to seven months with calciferol. Readings within, above, or below normal limits remained so in 43 of these cases, 34 of which were improving clinically, 8 showing no change, and there being 1 relapse. Similarly with the other 30 cases, where variations took place up or down the scale without relationship to the clinical progress. This test also is of no use as a "sensitive index" in lupus therapy.

Analysis of Plasma Proteins.—In a case which had been treated with calciferol for six weeks an electrophoretic analysis by Dr. A. Hoch (lecturer in chemical pathology at the London Hospital Medical College) gave the following distribution of the plasma proteins in g. per 100 c.cm., the normal electrophoretically determined range (Lewis and McCullagh 1944) being given in parentheses in each case immediately after the reading: total protein 7·5 (5·94–7·82), albumin 4·7 (3·72–5·11), alpha globulin 0·3 (0·39–0·66), beta globulin 1·2 (0·65–1·07), gamma globulin 0·8 (0·60–0·91), fibrinogen 0·45 (0·16–0·48). The alpha globulin is below normal in this case, the beta globulin is above normal, and the gamma globulin (currently regarded as the likely holder of antibodies) is within normal limits.

AIDS FOR THE CLINICIAN

On what aids, besides serial biopsies, may the clinician rely to assess progress or to warn him of danger in the treatment of lupus? Dowling (1946) points out that hypercalcæmia occurs erratically and is not related to the clinical progress of the case, and Meyer et al. (1946) are of the same opinion, but Ingram et al. (1946), in a preliminary report, state that in cases of intoxication the diffusible calcium is invariably raised. Also, Wigley (1946) mentions preliminary work which suggests that estimations of the blood-phosphatase may be found to be a reliable index.

In the present series useful aids were serial photographs by a technique evolved in the photographic department, and routine radiography of the kidneys and arteries for signs of calcification.

SUMMARY

The history of how calciferol (vitamin D_2) came to be used in the treatment of lupus vulgaris is summarised, and the clinical results of this treatment in 150 cases observed for four to twelve months are reviewed. Local treatment was also given in 87 of the cases, and general light baths in 14 cases.

The success attained during this time would have taken twice or three times as long before the introduction of calciferol therapy but in almost all cases the patient was now independent of general light treatment. The treatment appears to be increasingly efficacious for the first nine months. The proportion of resistant cases was virtually the same as it had been before the advent of calciferol.

The response of cases which had at any time been subjected to X-ray, radium, or Grenz-ray treatment was the same as that in cases not so treated. Calciferol had no effect on lupus carcinoma, but clinically potential malignancy was dispersed in at least 3 cases.

The incidence of intolerance was 23%, and when calciferol is given by mouth an alcoholic vehicle should be used. The addition of vitamin B was without effect on tolerance in 24 out of 25 cases. The addition of calcium increased tolerance of calciferol in 3 out of 42 cases, but was without additional clinical benefit. It is shown that the addition of calcium is not necessary.

There were signs of toxicity in 8 cases, but in the 2 cases where arterial calcification occurred it was possible to resume treatment with calciferol after an interval. It is suggested that the optimum dose has still to be determined, and that idiosyncrasy plays a part.

Estimations of the erythrocyte-sedimentation rate and lymphocyte-counts were of no value in assessing progress in lupus therapy. Clinical aids found useful were serial photographs and routine radiography of the kidneys and arteries for signs of calcification. Analysis of the plasma proteins in one case showed that the level of gamma globulin, regarded as the likely holder of antibodies, was average.

I wish to thank Dr. A. Burrows, Dr. W. J. O'Donovan, and Dr. H. B. May for all the necessary facilities, and Prof. J. R. Marrack and Dr. F. Prescott for suggestions in the preparation of this article. Sister Hall, of the lupus clinic, gave valued assistance in charting the data.

Pulmonary Tuberculosis

(E. L. S. and L. M. F.)

With a view to making certain that any changes noted in pulmonary tuberculosis were due solely to the calciferol, cases in the following categories were chosen:

(1) Chronic open cases not considered suitable for collapse therapy other than phrenic crush, and which had been treated by rest in bed for some time.

(2) Cases in which effective collapse therapy had been maintained for more than three months, and in which the sputum remained positive.

(3) Open cases awaiting thoracoplasty, since they might have to wait a long time for operation.

It did not seem desirable to try this treatment on cases with rapidly spreading disease, those with much toxæmia, or those clearly in the terminal stages of pulmonary tuberculosis. Two of the patients had lupus vulgaris also. A total and differential white-cell count was made on all cases; but since no well-marked improvement occurred in any cases a subsequent count was not done.

TREATMENT

The length of treatment varied from 20 to 50 days (average 41·8). The total dosage varied from 500,000 to over 3,000,000 units (average 1,844,500). The treatment was begun with 25,000 units of calciferol and 3 mg. of vitamin B_1 daily. If no complications developed, the dose of calciferol was then raised to 50,000 units a day, with vitamin B_1 as before. After a period on this dosage, if there were still no complications, the dose was raised to 100,000 units a day. The urine was examined before treatment was begun, and afterwards at weekly intervals.

RESULTS

The E.S.R. rose in 12 cases, in some patients considerably, and fell in 5 cases. In only 1 case did the temperature, when elevated before treatment, fall during treatment. Of the 10 patients who were up for a few hours during treatment, 3 gained weight, 5 lost weight, and 2 remained the same.

Sputum.—In 2 patients who had a negative sputum before treatment it remained so after treatment. In 16 cases the sputum was positive before and after treatment. In 2 cases with a positive sputum treatment produced a negative or no sputum. In 1 case there was no sputum before and after treatment.

Complications.—Headache was complained of by 7 patients during treatment. Nausea was a common complication, occurring in 16 cases, and the vitamin B_1, which was given with a view to mitigating this, appeared to have no effect. Anorexia was common; and in 4 patients vomiting made it necessary to stop the treatment. Albuminuria developed in 3 cases.

Most of these complications appeared when the dose was increased and the patient had been under treatment for some weeks. Drowsiness was noted in 1 patient, but most of the patients during the first few days of treatment reported that they felt distinctly stimulated.

CONCLUSIONS

No clinical improvement in the lung condition was noted in any patient.

The 2 patients who had lupus in addition to pulmonary tuberculosis both showed immediate improvement in the skin condition; 1 patient, however, who had lupus of the mucosa of the nares besides on the face, showed no improvement of the mucosa, and treatment had to be *discontinued quite soon because of vomiting.*

SAND-FLY FEVER

REVIEW OF 664 CASES

JOHN FLEMING
M.D. Glasg., F.R.F.P.S.
HON. COLONEL R.A.M.C.; PHYSICIAN, GREENOCK ROYAL INFIRMARY

IN Italy, during the autumns of 1943 and 1944, short-term fevers became increasingly frequent, until a major outbreak developed at the end of the war and in the autumn of 1945. Many of these fevers were probably abortive attacks of well-known febrile illnesses overcome by the reaction of the host before characteristic signs developed; we were probably dealing with many frustrated attacks of infective hepatitis, dysentery, atypical pneumonia, glandular fever, &c. This assumption gives reasonable sanction for the label "pyrexia of unknown origin" in the case of fevers lasting one or two days, but a very large group of these short-term fevers satisfied the rather ill-defined criteria for the diagnosis of sand-fly fever. This group, observed in a military hospital in Rome and another in Naples, is here reviewed.

THE VECTOR

There is no doubt that the case against the sand-fly *Phlebotomus papatasii* is complete, as numerous experiments have shown—e.g., Sabin et al. (1944), who studied 100 cases, many artificially infected by sand-flies. We doubt, however, whether the sand-fly is the only vector. In North Africa, where sand-flies were numerous enough to be readily visible, we saw in eighteen months very few cases of short-term fever of the sand-fly type, whereas they were numerous in Italy. There are undoubtedly sand-flies in the Naples area; but, even when this fever was epidemic, great difficulty was found in collecting sand-flies, though a large team of ex-patients was encouraged to look for them. In the Rome area the local physicians were emphatic that sand-flies were rare, though one of us (J. F.) saw more sand-flies in Rome than in the Naples area. On the other hand, culicine mosquitoes and *Stomoxys calcitrans* were in constant attendance during the whole epidemic period.

The fever is readily transmitted from an infected person to an experimental host by simple inoculation of blood-serum, as we demonstrated during the epidemic, and it seems possible that any blood-sucking insect may act as a minute hypodermic syringe, and larger insects are likely to be no less effective than the minute sand-fly.

Elkerton (1944), discussing oriental sore, has evidence that stomoxys may double the part of the sand-fly as infecting agent.

Gontaeva (1943), in an extensive investigation of 154 cases of sand-fly fever, could not find sand-flies in the area, but culicine mosquitoes were present.

Sabin et al. (1944) carried out control tests with the mosquito *Aëdes ægypti*, the gnat *Culex pipiens*, and the flea *Pulex irritans* with negative results.

Doerr et al. (1909) found that the bedbug *Cimex lectularius* could not pass the infection.

It has been estimated (Sabin et al. 1944) that 1000 infective doses per c.cm. of blood are required if this possibility of mechanical transmission is admitted. Our observations suggest that individual susceptibility may admit of considerable variation of infective dosage. Thus, though the present weight of evidence does not incriminate insect vectors other than *Phlebotomus papatasii*, such a possibility cannot be ruled out.

EPIDEMIOLOGY

During the two summers when short-term fevers were prevalent, the numbers in one hospital were as follows:

Period	*1–5 days' P.U.O.*	*Sand-fly fever*
Jan.-March, 1944	68	0
April-June, ,,	61	8
July-Sept., ,,	221	311
Oct.-Dec., ,,	68	9
Jan.-March, 1945	23	0
April-June ,,	266	576
July-Sept. ,,	120	606

During the Italian summer of 1944 there was an epidemic of short-term fever, including cases which could confidently be labelled sand-fly fever. The epidemic began in July and was maximal in August. In the summer of 1945, however, the epidemic was well under way in May and involved three times as many cases as in 1944. It is remarkable that sand-fly fever was so prevalent in the post-hostilities period, when living amenities were much improved and there was no observed increase in insect vectors. This raises the question whether the infective period may not in some cases be prolonged.

Immunity and Second Attacks.—Cullinan and Whitaker (1943), writing of an area of high infectivity, report second attacks 2–12 weeks after the first in 15% of cases. Livshitz (1937), from a study of experimental and natural cases, concludes that a single infection gives protection for 1–3 months, and that about 20% of patients could be reinfected during the same epidemic. He believes that there is a high degree of immunity in persons resident in endemic areas. This may explain the absence of sand-fly fever among the native population in Rome and Naples during the outbreak among British and American troops. In this series there were no cases of second infection; hence the above-mentioned conclusions about postinfective immunity cannot be checked.

Infectivity.—It may be fallacious to assume that the evidence for a short immunity period precludes the possibility that some cases may remain infective for many months. Sabin et al. (1944) found in their experimental cases that the blood did not remain infective later than forty-eight hours after the onset, but a convincing answer to this query seems to require transmission experiments in natural cases at various periods after recovery. Modhkovski et al. (1937), on the other hand, have demonstrated the transovular transmission of the virus of sand-fly fever to the next generation of insects, and that the females of the second generation can infect immediately after hatching. The large increase in the number of cases in 1945, as compared with 1944 and preceding years, may therefore be due to (1) a long period of infectivity following recovery in a number of cases, and/or (2) the facts that a large insect population was infected in 1944, and that increased battalions were waiting to begin operations in 1945.

BITES AND WEALS

It was notable that, among all the cases seen in two widely separated areas, there were very few exhibiting insect bites or giving a history of having been bitten. In the whole series of 664 cases only 7 had definite insect bites; all of these were profusely bitten, but none showed weals. It is well known that many people suffer little or no inconvenience from insect bites and do not develop itching or weals. It was impossible to make an extensive survey, but among 500 soldiers who gave a history of irritation and weal formation to culicine mosquitoes and *Stomoxys calcitrans* there was no-one who had been treated for a short-term fever. This suggests that those who develop a local reaction to the bites of insects may have special protection from the sand-fly and its infection. Possible factors are: (1) persons who react locally are likely to take more precautions against bites for their own comfort, if not for safety; and (2) the rapid development of a weal may localise the injected virus and neutralise it, unless the protective mechanism is overwhelmed by multiple bites. This may explain the only failure to infect a susceptible case in the series of Sabin et al. (1944) even after repeated bites. One of us (J. F.), though frequently bitten by sand-flies, did not develop the fever; but, as with other insect bites, the skin responded to each sand-fly attack with a large weal.

SYMPTOMS

Out of 664 cases considered in this report, in 624 the onset was sudden, with a rapid rise of temperature *during the first twenty-four hours to its highest point.* The distribution of symptoms was as follows: headache 638, retro-orbital pain 364, body pains 410, vomiting 116, photophobia 55, giddiness 20. The headache was usually severe and was often accompanied by pain on moving the eyes and behind the eyes. When photophobia was an added symptom, there was a close resemblance to early meningitis. Neck stiffness was noted in 121, and a definite Kernig's sign in 3. The body pains were localised to muscles in most cases, but 7 had chest pain resembling pleurodynia, and 3 had colicky abdominal pains. In 30 pain was localised in the larger joints, but there were no physical signs. Though vomiting occurred in 116, the great majority had no notable gastro-intestinal upset.

PHYSICAL SIGNS

Conjunctival injection was noted in 240 of the 664 cases, and this number included most of the cases showing palatal congestion; 100 had small vehicles on the palate. Rashes developed on the first day of illness in 95 cases: macular 30, urticarial 5, petechial 20, herpes labialis 40. Fine crepitations were noted in 9 cases, usually in the mid-zone of the chest, and 4 had cough but no sputum; radiography showed no evidence of pneumonitis. The spleen was enlarged in 10 cases; this sign was specially looked for owing to the frequency of malaria, but in view of the highly malarious state of the troops this number of enlarged spleens was not considered significant with regard to sand-fly fever.

The fever was typical; pyrexia lasted 2–5 days in 89%, and three days in 83% (550 cases). The onset of symptoms and fever was so rapid that the patients were first seen when the fever was at its height. There was no characteristic shape of the curves. The fever rose quickly to its highest point in a steady curve, but defervescence was invariably a staggered descent with every variety of peaks. In this series secondary fever did not develop.

At the height of the epidemic 1 c.cm. of blood-serum taken from a typical case was *injected intravenously* into a healthy recipient. From the latter, when his fever was established, 1 c.cm. of serum was injected into a second recipient. In *both cases typical three-day* fever with the usual symptoms developed two and a half days after the injection. In both cases the temperature followed a steady rising and falling curve, in sharp contrast to the irregular fall in the natural cases.

BLOOD FINDINGS

In a small series of 138 cases we were able in general to confirm the findings of Sabin et al. (1944). In most cases there was a leucopenia on the first day of illness, so the fall in white cells began during the incubation period. The white-cell count regained normal figures by the eighth or ninth day. During the fever there was a continued fall in the percentage of neutrophils, accompanied by a rise in the percentage of lymphocytes, producing a relative lymphocytosis. After the fever had subsided, the relative percentages rapidly regained normal proportions.

CENTRAL NERVOUS SYSTEM

In common with other virus diseases, sand-fly fever often produces some reaction in the central nervous system. Of the 664 cases, 80 had some indication of cerebral irritation severe enough to call for lumbar puncture. All the major symptoms of sand-fly fever can be related to cerebral irritation, and the cases which called for examination of the cerebrospinal fluid (C.S.F.) had similar but more acute symptoms: intolerable frontal headache, nuchal stiffness, and, in 3 cases, Kernig's sign, photophobia, and vomiting. In 70 cases the total protein in the C.S.F. was increased, the lowest amount being 20 mg. and the highest 130 mg. per 100 c.cm. There was a leucocytosis in 35 and a lymphocytosis in 30 cases. The average cell-count was 90, and the highest 360 per c.mm. Sabin et al. (1944), in the 5 cases of their experimental series which underwent lumbar puncture, report normal C.S.F. In our series 15 had normal cell-counts, but either the protein or the cell-count was high in every case. In 15 cases with severe headache the fluid pressure averaged 140 mm. H_2O, with extremes of 130 mm. and 210 mm. In 10 other cases the pressure was normal.

Pearson (1941) reports 15 cases of short-term fever with pronounced cerebral symptoms. He divides them into two groups—sand-fly fever and benign lymphocytic meningitis—but concludes that the latter is a syndrome common to "a group of diseases," of which sand-fly fever is one. We agree that the diagnosis of benign lymphocytic meningitis is, in any case, only provisional. Shee (1942) found, in 27 out of 30 severe cases of sand-fly fever, papillœdema to the degree of 2–2·5 dioptres.

There is, therefore, evidence that the sand-fly virus has a special affinity for the cerebral meninges, and should be considered in the differential diagnosis of meningitis in areas where the sand-fly is prevalent. Cases with pronounced cerebral symptoms all had protracted debility, and about half of these had some mental depression.

DIFFERENTIAL DIAGNOSIS

When met with in epidemic form, sand-fly fever presents no difficulty in diagnosis, but isolated cases or small numbers are a considerable problem. In such cases the diagnosis can only be presumptive when the fever subsides in one or two days, but in the average case there is time for investigation.

Malaria must be excluded by repeated blood smears; a malarial attack similar in intensity to the average case of sand-fly fever usually has easily demonstrable parasites in the peripheral blood.

Cases with signs of cerebral irritation call for immediate lumbar puncture to exclude *cerebrospinal meningitis.* The cell-count is lower than is usual in the febrile stage of *poliomyelitis. Atypical pneumonia* is unlikely if the temperature is normal on the third or fourth day and there are no physical signs in the chest.

The pre-icteric fever of *infective hepatitis* may be indistinguishable from sand-fly fever (Havens 1944, Dixon 1944), since gastro-intestinal symptoms may develop in both. Since the average sand-fly case will have recovered sufficiently to be discharged well within fourteen days, a mistake in diagnosis may mean that the supposed sand-fly case will develop jaundice after being discharged, to the discomfiture of the medical officer. The blood changes in sand-fly fever do not alone suffice to differentiate it from other virus and protozoal fevers causing leucopenia and relative lymphocytosis. In circumstances which justify it, a transmission experiment goes far to confirm the diagnosis by the precision of incubation period, fever, and symptoms. When both diseases are prevalent, this possibility must always be borne in mind. During the interval between fever and the onset of jaundice in infective hepatitis there is usually some indigestion, and the subcostal area is usually tender even if the liver is not already palpable.

SUMMARY

The clinical findings in 664 cases of sand-fly fever, treated in two military hospitals in Italy, are reviewed.

The epidemiology is discussed, and it is suggested that other biting flies besides *Phlebotomus papatasii* may be vectors, and that the possibility of protracted infectivity should be examined.

Evidence is adduced that persons who develop local skin reactions to the bites may have special protection against the infection.

The differential diagnosis is discussed; the blood findings were found to be of little help in differentiating sand-fly fever from other virus infections.

The virus of sand-fly fever has a special predilection for the meninges and should be considered in the differential diagnosis of meningitis in areas where the sand-fly is prevalent.

The fever is usually short and without sequelæ, but it had a high nuisance value and could cause a serious shortage of man-power and dislocation of services.

"... Britain has reason to be proud of its organisation for the treatment and social care of persons suffering from infantile paralysis and other crippling conditions. But these are the branches and leaves of the service; we must pay more attention to the roots. The work of the National Foundation in the United States should inspire us to devote more time and effort to research, to the study and the elimination of the causes of crippling disease. It would be short-sighted to confine attention to infantile paralysis alone, for there is a vast undiscovered country for research into allied conditions. Only recently an association has been formed for the care of children suffering from spastic conditions ... and St. Margaret's School, Croydon, has been opened as a research centre for the study of all aspects of this disability. What we need is a National Foundation for Research—'to lead, direct, and unify' the study of crippling conditions from the point of view of prevention. An organisation of this kind would be closely linked with the Medical Research Council, and its expert advisers would be drawn from universities, hospitals, and research institutions."—Special Correspondent, *Times*, March 24, p. 7.

PARAHÆMOPHILIA

HÆMORRHAGIC DIATHESIS DUE TO ABSENCE OF A PREVIOUSLY UNKNOWN CLOTTING FACTOR

PAUL A. OWREN
M.D. Oslo
From the University Hospital, Medical Department A, Oslo, Norway

UNDER the term parahæmophilia a form of hæmorrhagic diathesis previously unknown is described here. The condition is characterised by a greatly reduced coagulability due to the absence of a hitherto unknown clotting factor necessary for normal coagulation.

A woman, aged 29, was admitted to the University Hospital, Oslo, in 1943 with an abnormal tendency to hæmorrhage.

Her parents and eight brothers and sisters were alive and in good health. No hæmophilia in the family. She was healthy the first three years of life, and grew and thrived normally. At the age of 3½ years she had severe nose-bleeding without any known provocation. It ceased spontaneously in some hours. On the third and fourth days afterwards she had further bleedings, the latter so severe as to cause loss of consciousness. The hæmorrhage was stopped by plugging. Five days after the last epistaxis the parents noted that the child had greatly reduced vision, and next day she was blind. Two days later (11 days after the first hæmorrhage) she was referred to the University Hospital ophthalmological department. Amaurosis was demonstrated, with dilated reactionless pupils and choked disks, of 4–5 D. Hæmoglobin 28%. Otherwise normal findings on routine physical and neurological examination. Wassermann reaction negative. In 6 weeks the choked disks became atrophied. She was blind for 6 months, but later she recovered central vision in the right eye. The left eye was permanently blind. The bleeding-time and clotting-time were not determined.

At the age of 4½ years she again had a severe nose-bleeding and was readmitted to the University Hospital. The hæmorrhage was again stopped by plugging. Hb 38%; thrombocytes 1,000,000 per c.mm.; bleeding-time normal; clotting-time of whole blood at room temperature 70 min.

Later on in childhood she had frequent nose-bleedings, sometimes severe. She constantly developed bluish "contusion marks" and large extravasations of blood followed small injuries. At the age of 12 years she received a blow on the right elbow, causing an enormous effusion, with swelling of the entire arm from shoulder to fingers.

Menstruation began at the age of 14 years. During the first few years it was usually profuse and of long duration, with the result that she had to stay in bed during these periods up to the age of 20. On one occasion she had to enter a hospital because of severe menorrhagia. She was given blood-transfusions, which had a rapid hæmostatic effect.

In November, 1942, she had an attack of intense pain in the right side of the abdomen, accompanied by dysuria and dark urine. She cannot say with certainty whether the urine was hæmorrhagic, and it was not analysed. Otherwise she has felt well on the whole. She has never had a hæmarthrosis.

On examination in April, 1943, she was of small stature, but had no developmental anomaly. Bluish "contusions" were found on various parts of the body. Routine physical examination gave negative results. There were no petechiæ or telangiectases on skin or mucosæ, and no enlargement of spleen or liver. Blood-pressure and urine normal.

Blood Examination.—Hb 98%. Red cells 4,500,000 and white cells 7000 per c.mm. The red and white cells gave normal values on differential counts. Thrombocytes 400,000 per c.mm. (Nygaard's method). Normal thrombocyte morphology.

Bleeding-time (Duke) 4½–5 min. Clotting-time: whole blood, by capillary method, 15 min. (normal for the method 2–5 min.); whole blood in dwarf test-tubes at 37° C 25 min (normal time 5–10 min.).

Clotting-time of oxalated plasma with optimal recalcification in dilution 1 : 4 at 37° C 350 sec. (normal time 80–120 sec.). Clot retraction normal. Prothrombin-time (Quick) 70–80 sec (*normal 15–20 sec.*).

Fibrinogen 0·3%. Albumin 4·3%. Globulin 2·9%. Calcium 9·7 mg. per 100 c.cm. and phosphorus 3·6 mg. per 100 c.cm. in serum. Ascorbic acid 0·50 mg. per 100 c.cm.

In this case a hæmorrhagic diathesis was present, which had lasted since childhood. Clinically it manifested itself as skin-bleeding, nose-bleeding, menorrhagia, and possibly a minor renal bleeding. Examination demonstrated prolonged coagulation-time and prolonged prothrombin-time by Quick's method. It seems natural to conclude that the hæmorrhagic diathesis was due to a prothrombin deficiency, as the prothrombin-time recorded should correspond to a prothrombin concentration below 10% of the normal, a value which according to experience is accompanied by a tendency to bleeding.

So high a degree of hypoprothrombinæmia is known only in hypovitaminosis K and in severe hepatic damage. A thorough clinical examination, comprising liver-function tests, and investigation of the stomach, intestinal tract, and bile-ducts, revealed no sign of any such lesion; and the condition did not respond to large doses of vitamin K.

In view of these findings it was natural to doubt the correctness of Quick's method of prothrombin determination.

TABLE I—COAGULATION-TIME FOR PATIENT'S PLASMA AFTER ADDITION OF VARIOUS AMOUNTS OF FACTOR V

EXPERIMENTAL INVESTIGATIONS

Quick's method is based, according to the classical theory of coagulation, on the assumption that the speed of coagulation is proportional to the speed of formation of thrombin, which again depends on the concentrations of prothrombin, thrombokinase, and calcium. If an excess of thrombokinase is added to oxalated plasma, and this is recalcified with an optimal amount of calcium, the concentrations of thrombokinase and calcium are effectively constant. The prothrombin then becomes the only variable component, and consequently determines the speed of coagulation.

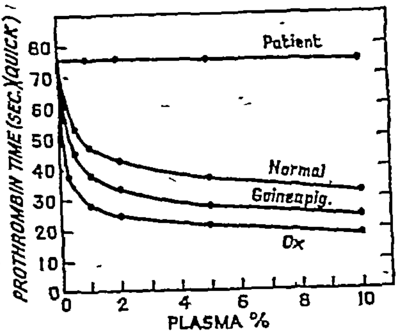

Fig. 1—Coagulation-stimulating effect on patient's plasma of small amounts of prothrombin-free plasmas examined by Quick's method for prothrombin determination.

In fibrinogen deficiency and in the presence of coagulation-inhibiting substances Quick's method fails. The fibrinogen concentration in this patient was normal (0·3%), and the reactivity of the fibrinogen to the thrombin was normal. The presence of substances inhibiting coagulation could also be ruled out, since the coagulation-time for normal plasma was not prolonged by addition of plasma from the patient.

To check the reliability of Quick's method, small amounts of plasma from normal persons were added to the patient's plasma, and the prothrombin concentration was determined by this method in the various mixtures. From the results it appeared that the prothrombin concentration increased more quickly than was anticipated from the amount of plasma added.

Prothrombin was then removed from various samples of normal plasma (two adsorptions with $Al(OH)_3$ followed by Seitz filtration), and variable quantities of this entirely prothrombin-free plasma were added to that of the patient. (Absolute freedom from prothrombin was proved by the absence of coagulation after addition of optimal amounts of thrombokinase and calcium.) The results (fig. 1) show that addition of prothrombin-free plasma caused diminution of the patient's "prothrombin-time" and consequently an apparent increase in the prothrombin concentration determined by Quick's method. Ox plasma and guineapig plasma had a greater effect than had human plasma, and prothrombin-free plasma from the patient was without effect, as anticipated.

Estimation of prothrombin by Quick's method failed, therefore, since the coagulation-time varied independently of the prothrombin concentration and depended on one or more additional factors in the prothrombin-free plasmas.

Normal conditions of coagulation in the patient's plasma could be restored by addition of 20% of prothrombin-free ox plasma. This effect of prothrombin-free plasma was unchanged after removal of fibrinogen (thrombin coagulation with subsequent inactivation of the excess thrombin by leaving for 30 min. at 37° C) and thrombokinase (Chamberland's filtration). The active factor which restored normal conditions of coagulation in the patient's plasma, therefore, could not be prothrombin, thrombokinase, calcium, or fibrinogen.

On the basis of these and other confirmatory tests it was concluded that the patient's blood lacked a substance found in normal blood and necessary to normal coagulation. This substance is not included in the classical theory of coagulation or in later theories of coagulation. This factor I have termed the fifth clotting factor—factor V. I have isolated this factor entirely free from the previously known factors of coagulation.[1]

Table I shows how addition of the isolated factor V produced normal coagulation in this patient after recalcification of the oxalated plasma, and after recalcification following the addition of thrombokinase by Quick's method. This latter test illustrates how Quick's so-called "prothrombin-time" may vary independently of the prothrombin concentration and depends on factor V.

In another test factor V was isolated from 100 c.cm. of normal plasma, sterilised by filtration, and injected into the patient intravenously. She experienced a slight shivering fit but no other reaction. One hour after the injection the coagulation-time after optimal recalcification of oxalated plasma was reduced from 340 sec. to 170 sec., and Quick's "prothrombin-time" had decreased from 65 sec. to 28 sec. The effect decreased gradually and entirely disappeared after 3 days.

The isolation of factor V and its function in the coagulation process are discussed in detail elsewhere,[1] evidence being adduced that pure prothrombin is not converted into thrombin by addition of thrombokinase and calcium alone. The formation of thrombin requires the presence of factor V, and the velocity of this reaction increases with increasing amounts of factor V up to a certain limit (fig. 2).

CONCLUSIONS

To summarise, thrombin formation may be expressed as follows:

Prothrombin + Factor V + Thrombokinase
+ Calcium → Thrombin.

I have demonstrated[1] that this reaction falls into two stages: (1) the formation of the actual prothrombin-converting enzyme, termed factor VI; and (2) the conversion of prothrombin to thrombin under the influence of factor VI in the presence of calcium. Factor V acts as a pro-enzyme for factor VI.

Parahæmophilia is caused by failure of the formation of factor VI owing to the lack of factor V. In hæmophilia the reaction is delayed because of the lack of free or active thrombokinase. In both cases the result is identical: a deficient formation of thrombin and consequent delayed and incomplete coagulation. This similarity in the pathogenic mechanism, together with the similarity in the clinical picture, justifies the designation parahæmophilia.

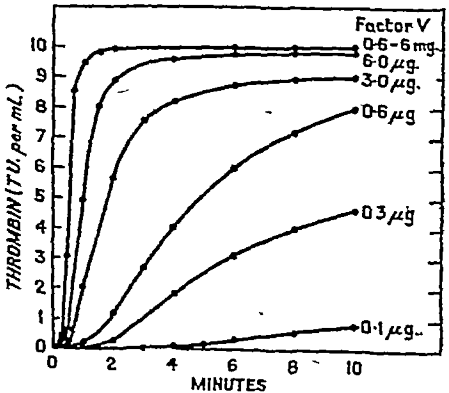

Fig. 2—Speed of thrombin formation by optimal concentration of thrombokinase and calcium and various amounts of factor V: prothrombin, 10 prothrombin units per c.cm. of mixture; thrombokinase, human brain (treated with acetone) in optimal concentration; calcium, 2·5 mM.; temperature, 37° C; pH, 7·3.

Factor V deficiency is a more adequate description of this lesion, but such a designation should be postponed until factor V has been given a more suitable name.

The differential diagnosis between parahæmophilia and hæmophilia is easy, as the faulty coagulation of parahæmophilia is not returned to normal by addition of thrombokinase as in the case of hæmophilia. Table II illustrates this relation by the use of various thrombokinase preparations.

---

[1] Owren, P. A. *Proc. Norwegian Acad. Sci.* 1944, p. 21; *Acta med. scand.* (in the press.)

Parahæmophilia is rare, but the faulty coagulation demands considerable attention. This new knowledge of the coagulation process shows, among other things, that the usual methods of quantitative prothrombin determination are based on a dubious foundation, and it will influence our ideas about the pathology of prothrombin. The rôle played by factor v in clinical pathology will be the subject of further investigations.

SUMMARY

An account is given of a woman with a hæmorrhagic diathesis which had lasted since childhood, and had manifested itself by skin-bleedings, nose-bleedings, menorrhagia, and probably an isolated renal bleeding.

Prolonged coagulation-time and prolonged prothrombin-time by Quick's method were demonstrated.

The causal factor was not prothrombin deficiency but lack of a previously unknown coagulation factor named factor v.

The lesion has been termed parahæmophilia. It is probably not hereditary.

EFFECT OF WATER ON GASTRIC MOTILITY

A TEST FOR DUODENAL ULCER

ANDREW W. KAY
M.D. Glasg., F.R.C.S.E.
From the Peptic Ulcer Clinic, Western Infirmary, Glasgow

WHEN a recording balloon on the end of a Ryle's tube is introduced into the fasting stomach of normal man, the gastrogram obtained shows four types of waves. Two of these, respiratory and cardiac oscillations, are superimposed on the intrinsic waves resulting from changes in the intragastric pressure. The true gastric contraction is represented by a sharp-topped wave lasting 30 sec.; a less abrupt regular wave depicts a slow rise and fall of intragastric pressure caused by tonic contractions of the fundus—tonus rhythm (fig. 1).

Carlson (1916) observed that the ingestion of cold water inhibited gastric contractions for about 5 min. Anderson (1943) confirmed this inhibition, lasting 10–35 min., in normal subjects but not in patients with peptic ulceration, in some of whom the ingestion of cold water even stimulated gastric contractions. This abnormal response he called the "water reversal phenomenon."

This paper presents the results of an investigation on the effect of water on gastric motor function. The aims have been to investigate the physiological basis for the water response and to explore the possibility of its application to the diagnosis of duodenal ulcer.

METHODS

Gastric motility has been recorded by a modification of Carlson's technique, with the patient fasting, the swallowed balloon inflated to a standard pressure of 10 cm. H_2O, and a tambour-kymograph unit used for recording (fig. 2). Patients find this investigation less tedious and no more unpleasant than a fractional test-meal. To test the effect of water on gastric motility, the patient is given a small draught of tap water, or, if a double tube has been swallowed, 20 c.cm. of water is injected through the stomach-tube, and the test is signalled on the tracing.

RESULTS

The effect of water on gastric motor function was observed in normal subjects and in patients with active duodenal ulcer. In the normal group gastric motility was inhibited for about 5 min. (normal response); in the ulcer group either activity was increased (reversed response type I) or, where contractions were already well developed, existing activity persisted (reversed response type II) (fig. 3). In both groups the latent period was 45–60 sec.

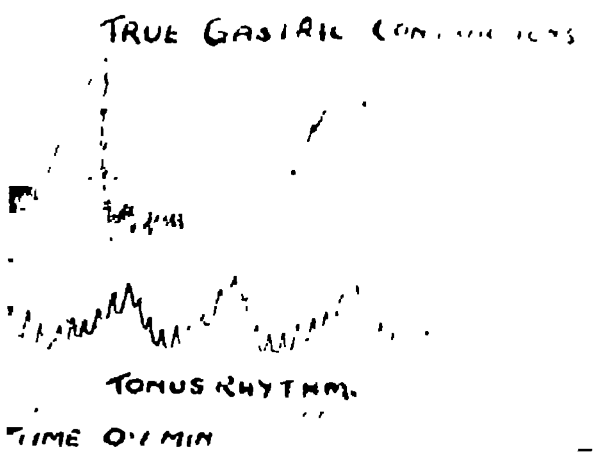

Fig. 1—Tracings of true gastric contractions and of tonus rhythm.

This confirmation of the observations of Carlson and Anderson seemed to justify a study of the physiological basis and possible diagnostic application of the gastric motor response to water.

PHYSIOLOGICAL BASIS

Site of Action.—Carlson believed that the inhibitory effect of cold water on gastric motility was due to afferent stimuli arising in the gastric mucosa. The modification of this response observed in patients with duodenal ulcer has led me to the view that the receptor for this reflex is in the duodenum. In support of this hypothesis, the following observations are offered:

I found that water, coloured with azorubrum, could be aspirated from the duodenum within 45 sec. of ingestion. Since the time taken by water to pass the pylorus corresponds to the delay in the development of the subsequent gastric motor response, it seems probable that the receptor point for the response is in the duodenum. This is supported by the results of a further experiment.

In 4 patients with gastric and duodenal tubes in situ 20 c.cm. of water at room temperature was introduced first into the duodenum and secondly into the stomach. After duodenal injection the latent periods for the water response were 18, 15, 20, and 22 sec.; after gastric injection the corresponding latent periods were 50, 45, 50, and 55 sec.

The fact that the water stimulates gastric contractions when the ulcer is duodenal but not when it is gastric (see below) also suggests that the receptor point is in the duodenum. When the duodenal ulcer has completely healed, the reversed response to water gives way to a normal response (see below).

Effect of Solution Tonicity.—The introduction of hypertonic solutions into the stomach is known to cause protracted inhibition of gastric motility in normal subjects. It therefore seemed useful to investigate the effect of solutions of different tonicity in cases of duodenal ulcer. In 15 patients with duodenal ulcer 20 c.cm. each of water, normal (0·9%) saline, 2% saline, 5% saline, and 10% saline, again at room temperature, was introduced into the stomach, and the gastric motor responses were recorded. As the test solution became more hypertonic an increasing number of patients gave a normal response (inhibition); in 14 patients 10% saline effected inhibition (fig. 4).

It therefore seems that, though water abolishes gastric activity in normal subjects, the stronger stimulus of hypertonic solutions is required in patients with duodenal ulcer.

Effect of Temperature.—The temperature of the water does not influence the type of gastric motor response but merely alters the duration of the response. In normal subjects I found that cold water (10° C) had a slightly longer inhibitory effect than hot water (50° C). Similarly,

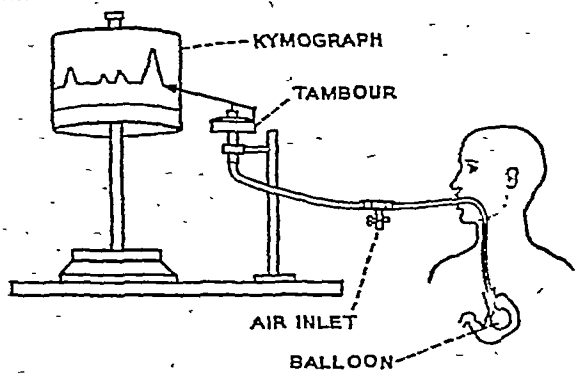

Fig. 2—Method of recording gastric contractions.

in duodenal-ulcer patients cold water had a longer excitatory effect than hot water. The type of response was always recognised without difficulty.

CLINICAL APPLICATION

To be of value in diagnosis (1) the water reversal response must be given consistently in patients with active duodenal ulcer; (2) it must be replaced by a normal response when the ulcer has healed; (3) it must not be given by other common causes of dyspepsia, such as gastric ulcer and gastric carcinoma; and (4) its inherent fallacies must be defined. The extent to which these criteria are fulfilled has been investigated:

(1) In 30 normal subjects the ingestion of water inhibited gastric contractions. In 90 patients with symptoms of duodenal ulcer and showing a crater on X-ray examination the water excited gastric contractions, gastric motility being increased in 68 and well-developed activity maintained in 22:

		GASTRIC CONTRACTIONS		
Condition	*Cases*	*Inhibited*	*Increased*	*Maintained*
Normal ..	30	30	0	0
Active D.U. ..	90	0	68	22

(2) To ascertain the effect of healing of the duodenal ulcer on the gastric response, the water test was applied to 15 patients who had remained symptom-free for at least a year after perforation of a duodenal ulcer and without any radiological evidence of activity. This group was chosen on the assumption that the ulcers had completely healed. A normal response (inhibition) was obtained in all cases.

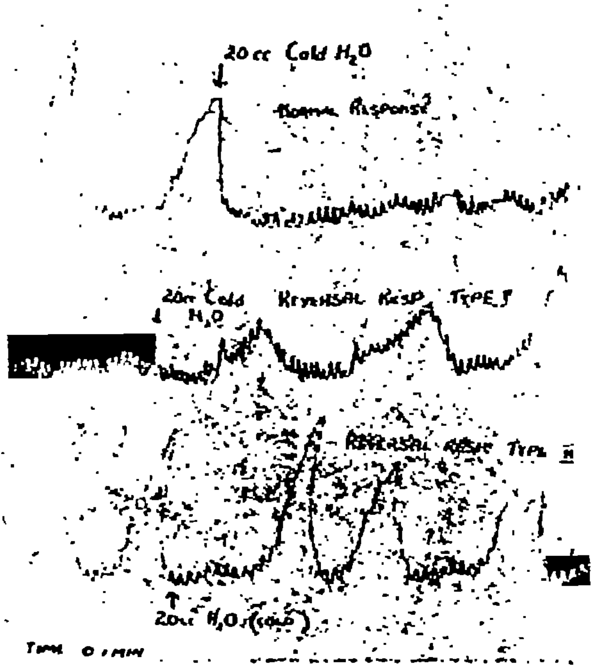

Fig. 3—Tracings of gastric motor responses to water test.

(3) The water test was applied to 34 patients with definite gastric disease (ulcer 12, carcinoma 22). A normal response was obtained in 33 patients. A reversed response was recorded in 1 patient with carcinoma of the stomach in whom, however, invasion of the duodenum was revealed at laparotomy.

(4) Carcinomatous involvement of the duodenum is so rare that it scarcely merits consideration as a possible fallacy in the water test. The only likely fallacy so far noted has been in patients with acute inflammation of the gall-bladder. Of 9 such patients investigated, in 2 the water test excited gastric contractions, and in 1 of these laparotomy revealed an empyema of the gall-bladder with adherent duodenum.

DISCUSSION

A gastric ulcer can usually be revealed with certainty with the aid of radiography and gastroscopy, but a duodenal ulcer cannot be so easily recognised. Endoscopy of the duodenum is not yet practicable, and the radiological demonstration of an ulcer crater in the duodenum is difficult. Thus Templeton (1944) reported 809 cases of clinically active duodenal ulcer in only 526 (65%) of which a crater could be demonstrated. The gastric response to water is proposed as a test to decide whether or not there is a clinically active duodenal ulcer. This test has the advantage of being objective, whereas the personal factor is an inherent weakness of radiological investigation.

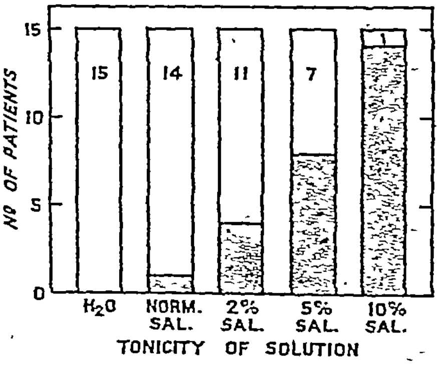

Fig. 4—Gastric motor responses in 15 patients with duodenal ulcer showing return of normal response (inhibition) with increasing tonicity of ingested fluid.

Besides its use in diagnosis, the gastric motor response to water may be used to test the healing of a duodenal ulcer. The gastro-enterologist who tries to assess the relative merits of various "cures" for duodenal ulcer quickly encounters difficulty in choosing an end-point for the healing of the ulcer. The absence of pain and of occult blood in the stool does not provide satisfactory evidence. The radiological disappearance of the ulcer crater almost certainly precedes actual healing. The gastroscopists have in fact shown that gastric ulcers often become "radiologically negative" for an appreciable time before complete healing is found gastroscopically. I suggest that the return of the normal gastric response to water (inhibition of contractions) is a dependable criterion of healing. Gastrograms are being recorded in duodenal-ulcer patients who become symptom-free and cease to show a crater on radiography. So far I have found that the gastric motor response to water may remain abnormal for as long as four weeks after a barium meal has shown no signs of ulceration.

SUMMARY

Ingestion of cold water inhibits gastric motility in normal subjects for about 5 minutes; hot water has a similar but briefer effect.

In the presence of active duodenal ulcer gastric activity is either unaltered or even stimulated by the ingestion of water.

The water test is therefore of value in the diagnosis of duodenal ulcer.

Evidence is presented which indicates that the receptor point for this gastric response to water is in the duodenum.

This duodenal mechanism, which normally inhibits gastric motor activity, is damaged by active ulceration but functions normally when the lesion has healed.

The water test can therefore be used to provide reliable evidence of healing.

I am indebted to my colleagues in the radiological department of the Western Infirmary, and to Prof. C. F. W. Illingworth for his direction and helpful criticism throughout this investigation.

Medical Societies

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY

Tubal Patency Tests

ADDRESSING this society on March 20 Dr. MARGARET HADLEY JACKSON said that disorders of the fallopian tubes are commonly held to be a causative factor in nearly half all cases of infertility. Of 570 cases submitted by her to tubal patency tests, not much more than 30% had any tubal disorder (including complete occlusion, partial or temporary occlusion by spasm or stenosis, and lack of normal tubal peristalsis). This figure is lower than that of most workers. Moreover, after repeated patency tests total organic occlusion was present in only about 10%. If routine tubal patency tests are not carried out the cause of some cases of sterility will be missed. It should be remembered that the indications for these tests are not only diagnostic but also therapeutic, since pregnancy quite often follows.

With acute pelvic infections patency tests are naturally contra-indicated. The best time for doing them is during the middle third of the menstrual cycle—well away from menstruation, as near as possible to the date of ovulation and preferably just before it. With the patient in the lithotomy position, a bivalve plastic speculum is inserted; not more than 150–200 c.cm. of CO_2 should be used and pressure should never exceed 210 mm. Hg.

Gentleness and asepsis are essential; antispasmodics should be given whenever there is spasm; but anæsthesia is rarely necessary, and is indeed a disadvantage since the patient's coöperation is needed at the operation. Moreover, anæsthesia does not relieve tubal spasm. The operation causes slight pain rather like that of mild dysmenorrhœa, unless there is obstruction or unless pressure is raised unduly, whereupon mid-hypogastric pain, sometimes referred to the sacrum or iliac fossæ, ensues. The patient rarely feels sick or faint, and the whole procedure is often completed without her being conscious of anything more than the insertion of the speculum. Late effects include transient and usually moderate shoulder pain on sitting up or, after the use of iodised oil, pelvic and sacral aching. The importance of repeating the tests before accepting a diagnosis of complete occlusion cannot be over-emphasised.

Tubal insufflation and iodised oil injection are complementary tests. Insufflation is inexpensive and not troublesome, taking only about 10–15 minutes. With a regularly tested kymographic apparatus peristaltic movements, spasms, and stenosis of tubes can be accurately recorded; a volsellum need hardly ever be used. On the other hand, with insufflation alone it is impossible to be sure whether both or only one tube is patent; nor can a block be located; air-embolism and sepsis are possible but avoidable dangers. By means of uterosalpingography the shape, size, and position of the uterus and of the cervix can be visualised; filling defects and spasticity can be shown; fixation of the uterus can be demonstrated by screening; and the length and tortuosity of tubes and points of obstruction or occlusion noted. Moreover, iodised oil has a therapeutic effect; but the procedure takes longer and is more expensive, and since a volsellum is necessary it is more painful.

Reviews of Books

The Embryology of Behaviour

The Beginnings of the Human Mind. ARNOLD GESELL, M.D., PH.D., SC.D., in collaboration with CATHERINE S. AMATRUDA, M.D. London: Hamish Hamilton. Pp. 289. 21*s*.

WITH some nineteen previous books on child development behind him, Dr. Gesell has produced a twentieth which is perhaps the most ambitious to date. In this he and his collaborator attempt to "indicate how an organic complexus of behaviour is built up concomitantly with the bodily development of the embryo, fœtus, and neonate." The authors do not, however, appear to have been quite clear whether they were to produce a popular book or a serious contribution to scientific knowledge. The result in either case is somewhat unsatisfactory. This is particularly true of the sections dealing with antenatal development. Though profusely illustrated (largely from the works of other writers), they fail to give either a clear outline of what has been established experimentally about fœtal behaviour, or to add materially to it. Once birth is over, Dr. Gesell is on more familiar ground. The substance of the book is essentially the results of intensive study, by photographic and other methods, of some 22 premature infants admitted to the World's Fair Hospital (Infant Incubators Inc.). It has thus been possible to construct for different stages of prematurity certain behaviour norms comparable to those the author has previously established for full-term infants. This is a valuable piece of observation, and it is perhaps a pity that a study of behaviour in prematures should have been given a somewhat misleading title.

Radiologic Examination of the Small Intestine

ROSS GOLDEN, M.D., professor of radiology, Columbia University, New York. London: J. B. Lippincott. Pp. 239. 36*s*.

RADIOLOGICAL study of the small intestine has progressed very slowly, and until recent years only gross abnormalities were accurately reported. Prof. Ross Golden has long been attempting to correlate radiological abnormalities of pattern and motility with the clinical findings of diarrhœa, intestinal bleeding, and abdominal pain. This volume, the fruit of many years' laborious research, advances our knowledge considerably. He rightly insists that we need to know the basic facts about the action and control of the small intestine; and the first 50 pages deal only with the normal. There is a good chapter on the use of the Miller-Abbott tube for so-called small-intestine enemata. Appearances in disorders of nutrition are given much space, and changes in the earlier and less defined cases have been compared with findings in more advanced cases as they improved under treatment. This study had yielded much new information on abnormalities of bowel pattern with varying disturbances of motility. Professor Golden suggests that radiologists should abandon the term "deficiency pattern," since similar appearances can be produced by many conditions other than vitamin deficiency, and proposes instead "disordered motor function." Inflammatory disorders and tumours are considered in great detail, and there are good chapters on allergy and the action of drugs. He is well aware of the great gaps in our knowledge; but his work has gone an appreciable way towards filling them.

In the 15th edition of Pye's SURGICAL HANDICRAFT (Bristol: J. Wright, pp. 668, 25*s*.) Mr. Hamilton Bailey has supplemented the text with many new photographs and diagrams, and has presented material concisely under clear headings. His list of contributors should ensure that confidence in this trusted book is maintained.

The British mission of the Allied Control Commission to Rumania has published a stout loose-leaf volume on PENICILLIN, being a compendium, in Rumanian, of the British papers on the subject published in the last year. This able piece of work, which has been done entirely on the initiative of members of the mission, has been warmly welcomed by Rumanian doctors and their government. It sets an example which ought to be followed widely.

Stimulus to Intestinal Peristalsis

I-SO-GEL, a granular preparation of certain dried mucilaginous seeds, has the property of reproducing the normal stimulus to intestinal peristalsis by increasing the intestinal bulk, through absorption of water in the alimentary canal.

I-SO-GEL contains no purgatives and is a purely natural laxative with a smooth mechanical action, specially suitable for the constipation of diabetes.

It is valuable also in mucous colitis, dysentery, hæmorrhoids, and intestinal flatulence. After the performance of colostomy, I-so-gel gives excellent results by solidifying the fæces.

In bottles at 4/6 *and* 16/10 *each, including Purchase Tax*

B.D.H. SEX HORMONES

The B.D.H. range of sex hormone products includes preparations for the treatment of all forms of gonadal deficiency Synthetic œstrogens also are available

ANDROGENS

TESTOSTERONE PROPIONATE B.D.H. — testicular hormone ester Ampoules of solution for injection

METHYL-TESTOSTERONE B.D.H. — testicular hormone derivative Tablets for oral administration

ŒSTROGENS

OESTROFORM — ovarian œstrogenic hormone, free and esterified Ampoules of solution for injection Tablets for oral administration Pessaries for vaginal administration Ointment for topical application

DIENŒSTROL B.D.H. — synthetic œstrogen of low toxicity Tablets for oral administration

STILBŒSTROL B.D.H.—the most generally used synthetic œstrogen Tablets for oral administration Ampoules of solution for injection

STILBŒSTROL-D.P. and HEXŒSTROL B.D.H. — synthetic œstrogens which are sometimes better tolerated than stilbœstrol itself Tablets for oral administration Ampoules of solution for injection

PROGESTOGENS

PROGESTIN B.D.H. — hormone of the corpus luteum Ampoules of solution for injection

ETHISTERONE B.D.H. — a derivative of progestin Tablets for oral administration

The Crisis and the Service

ONE effect of the economic crisis is that the Government are being urged to drop their programme of nationalisation and give their whole attention to the needs of today. The suggestion has been heard that they may be obliged, among other things, to postpone the establishment of the National Health Service, and this suggestion seems to be associated with an idea that the task of bringing the service into being is too great to be accomplished in the twelve months remaining before the appointed day. In political life, of course, hardly anything is certain; and it is possible that before April 1, 1948, we shall have another Government or that the present Government will have departed from its firm intention to carry the scheme through. For anyone to count on any such a possibility, however, would be most unwise, and there is no reason to think that the arrangements required under the Act cannot be made in the allotted time. The machinery of hospital administration will soon be coming into action: by next month at latest the regional boards will be constituted; their first duty will be to appoint the management committees; and the transition from one form of management to another presents no insoluble problems. On arrangements for medical practice, the proceedings of the Negotiating Committee are wrapped in silence; but we shall not be far wrong in guessing that, with concessions on both sides, the differences between the Minister and the committee will be narrowed to one or two issues. It seems likely, too, that having considered these issues the profession will ultimately decide on participation in the service; and, if that is so, it would be well to make the decision as soon as possible. The earlier it is reached, the more time there will be for settling details in advance, and the less chance there will be of injustices and confusion that would benefit neither patient nor doctor.

If we are right in thinking that the National Health Service will be introduced according to schedule, we are left nevertheless with the disquieting question whether the economic situation will seriously damage its quality and development. Medical services are not necessarily any more expensive to the nation if they are maintained by the citizen as taxpayer rather than as private person; but to many people they appear so; and their progress is necessarily related more closely to the state of the Exchequer. If therefore the change to State ownership coincides with a big effort to reduce the weight of taxation there is danger that developments—even some which might have been possible under the old system—will be prevented by the general policy of keeping down all Government expenditure. The fact that it has to be raised in taxes and compulsory contributions might thus for a time make it harder, rather than easier, to find money for new hospitals, new health centres, and new health-workers.

But whatever the method of financing the service —and whatever Government is in power—the fundamental question will be: can a country in our position afford to devote more materials and man-power to medical work when these are needed for essential industries? If, as is probable, this question arises, we must be ready to show that efficient medical services are as necessary to a modern nation as they are to a modern army. If he is to give his best under difficulties the civilian, like the soldier, needs the best possible medical backing. And the full contribution which medicine can offer to national recovery cannot be made without large material improvements in many of the hospitals, clinics, and surgeries in which we now work at so much disadvantage.

Acholuric Jaundice

THE retirement of Prof. H. M. TURNBULL, F.R.S., from the department of morbid anatomy at the London Hospital has been marked by a special number of the *Journal of Pathology and Bacteriology*, all the contributors to which are his former pupils. Since the morbid anatomy of blood diseases is one of Professor TURNBULL's interests, it is appropriate that the articles should include one by LOUTIT and MOLLISON [1] on the classification of hæmolytic icterus (acholuric jaundice) into congenital and acquired types.

Ever since 1907, when CHAUFFARD first described the disease and WIDAL distinguished congenital and acquired forms, this division has been a source of controversy. The congenital or familial form usually presents a clear-cut clinical picture—recurring attacks of anæmia and jaundice appearing in childhood or early adult life; an enlarged spleen; a variable anæmia, sometimes severe, with most of the red cells appearing as small densely staining spherocytes showing excessive fragility in saline solutions; and signs of active hæmolysis, such as reticulocytosis, normoblastic hyperplasia of the bone-marrow, and high serum bilirubin with increased pigment excretion in the fæces but no bilirubin in the urine. The characteristic morbid anatomy of the spleen was graphically described by TURNBULL [2] as "conspicuous narrow venous capillaries in a lake of blood." The acquired form is much more vague: it appears later in life and is clinically more severe; the spleen is not so prominently enlarged; neither increased fragility of the red cells nor spherocytosis is so pronounced; and splenectomy often brings only partial relief, in contrast with the clinical cure in the congenital cases. There is no doubt that many of the acquired cases described were really hæmolytic anæmias secondary to some identifiable condition, such as secondary malignancy in the bone-marrow, but there remains a group of cases that appears to be primary.

Quantitative fragility tests revealed that many of the relatives of patients with congenital hæmolytic icterus had a minor but detectable spherocytosis and increased fragility of the red cells. It was then supposed that the primary defect was in the erythropoietic tissue of the bone-marrow, where spherical, unduly fragile red cells were produced instead of the

normal biconcave disks; and this applied to congenital and acquired cases, the only difference being one of degree. NAEGELI[3] together with DAWSON[4] and VAUGHAN[5] in this country and TILESTON[6] in America were among the supporters of this view, but MEULENGRACHT[7] maintained that the two conditions were separate and that acquired hæmolytic icterus was really a group of different diseases. Support for MEULENGRACHT's view came from several sources. In 1920 EPPINGER[8] had described, in addition to the splenic congestion typical of the congenital syndrome, at least two other histological pictures in the spleen in cases of hæmolytic jaundice—a pronounced histiocytic hyperplasia, sometimes associated with extramedullary hæmopoiesis, and one in which there were numerous small thromboses of capillaries and veins and consequent fibrosis. Such cases were described in this country by DAVIDSON[9] and by ISRAËLS and WILKINSON[10] in patients showing increased red-cell fragility and spherocytosis but with no detectable family history. The theory that spherocytes are produced only by a congenitally abnormal marrow received its most damaging blow from DAMESHEK and his co-workers in Boston,[11] who showed that spherocytes could be artificially produced in animals by the intravenous injection of hæmolysins, and that by varying the dose a whole range of hæmolytic syndromes, resembling the human syndromes from acute to chronic, could be produced. Their experiments led them to the view that spherocytes are formed outside the bone-marrow by the action of a hæmolytic agent on mature cells only, so that spherocytosis—and the parallel increase in red-cell fragility—is simply an indication of excessive intravascular hæmolysis. They again put the congenital and acquired varieties into one large group, the only difference being in the "dose" or effectivity of the hæmolytic agent; the symptomatic acquired cases—anæmias secondary to definite diseases like Hodgkin's disease, lymphosarcoma, and so on, or to drugs or poisons—were included; and SINGER and DAMESHEK[12] described 7 examples of secondary acquired hæmolytic icterus, 6 of which had spherocytosis and increased fragility of the red cells. Unfortunately, it proved rarely possible to demonstrate the hæmolysin, and the cases in which it could be demonstrated fell into the acquired group. Moreover, the hæmolysin may be only irregularly detectable; thus in a case described by STACEY[13] an autohæmolysin was demonstrable during a hæmolytic crisis but could not be found eight weeks later when the patient was clinically improved. The Boston school were obliged to postulate subdemonstrable concentrations of hæmolysin and prolonged or sudden action—a not very satisfactory explanation.

LOUTIT and MOLLISON[1] have now tackled the problem from a new angle. They have studied the survival of red cells in these patients, and have looked for evidence of sensitisation to hæmolysins by testing against a suitably prepared anti-human-serum serum. Completely opposing results were obtained in the congenital and acquired cases. In congenital hæmolytic icterus, normal red cells transfused into a patient survive normally; the patient's red cells transfused into a normal recipient survive only a short time (50% survival after 5–15 days, compared with the normal 50–60 days); and the cells are not agglutinated by anti-human-serum serum. After splenectomy, even when the patient is clinically cured, the patient's red cells are still rapidly destroyed by a normal recipient. In acquired hæmolytic icterus, normal red cells transfused into a patient survive only a short, or sometimes very short, time; the patient's red cells transfused into a normal recipient survive normally; and the patient's washed red cells are agglutinated by anti-human-serum serum. After splenectomy, the destruction of transfused normal cells is sometimes less rapid; clinical relief varies and is usually only partial. From these results LOUTIT and MOLLISON conclude that in the congenital form there is no evidence of any circulating hæmolysin or excessive activity of the reticulo-endothelial system; it is the red cells of these patients that are abnormally sensitive to the *normal* hæmolytic processes. In the acquired form there is no evidence of any abnormality of the red cells, but there is evidence of an intravascular hæmolysin that is rapidly destroying any circulating red cells—whether the patient's or transfused. They still agree with DAMESHEK and SCHWARZ that spherocytes are produced by the action in vivo of hæmolysins and are not produced by a congenitally abnormal marrow.

The ætiology of congenital hæmolytic icterus as proposed by LOUTIT and MOLLISON is as follows. Erythropoiësis is congenitally defective but the cells do not leave the marrow as spherocytes; they are unduly sensitive to normal lytic processes, and these, acting intravascularly, produce the spherocytic form. LOUTIT and MOLLISON think that lysolecithin may be the lytic agent responsible. It has been shown[14] that this substance acts particularly in the spleen when the blood is slowed in its passage through this reservoir. There is evidence, too, that red cells in the splenic vein show greater spherocytosis than those in the splenic artery, and a substance with the properties of lysolecithin has been extracted from splenic-vein blood. This would explain why clinical cure and a great diminution in all the signs of hæmolysis may follow splenectomy, even though the congenital defect of the red cells is unaltered. The acquired cases LOUTIT and MOLLISON regard as secondary, even when the original source of the abnormal hæmolysin cannot be identified, and they therefore urge that all these cases should, when possible, be classified according to their ætiology rather than on the red-cell changes that indicate only hæmolytic activity. MAEGRAITH and colleagues[15] have suggested that the hæmolysis in blackwater fever is due to a disturbance of the normal balance between tissue hæmolysins and lysin inhibitors in serum, the inhibitory power being much reduced. A similar disturbance may be the ætiological factor in the cases of acquired hæmolytic icterus in which no abnormal hæmolysin can be detected.

Thus, what we know today confirms Widal's original idea that there are two clinically and ætiologically distinct forms of hæmolytic icterus: one, sometimes familial, in which abnormal red cells are rapidly destroyed by normal lytic processes; and another, with no familial element, in which normal red cells are rapidly destroyed by abnormal lytic processes. It remains to find suitable names: spherocytosis applies to both, so "familial spherocytic anæmia" and "secondary spherocytic anæmia" would be short descriptive terms; or, with Loutit and Mollison, we might be more explicit and term them familial and secondary hæmolytic anæmias of spherocytic type.

Treatment of Myasthenia Gravis

The neuromuscular defect in myasthenia gravis has been the subject of much research in the last few years, and its mechanism is becoming clearer. Clinical observation suggested that the essential defect was in transmission at the myoneural junction, and this was proved conclusively by Harvey and his colleagues[1] in 1941. There were three possible reasons for the interruption—too little acetylcholine might be produced; the acetylcholine might be destroyed abnormally rapidly by cholinesterase; or some substance similar in action to curare might block the action of acetylcholine. The last view was strongly supported by Wilson and Stoner,[2] who tested the serum of patients with myasthenia gravis on the isolated nerve-muscle preparation of the frog and found that it blocked neuromuscular transmission if the patients were not receiving 'Prostigmin,' whereas serum collected from patients during prostigmin treatment had no effect.

The first advance in treatment was an empirical one. In 1930 Edgeworth[3] found that ephedrine relieved the weakness of myasthenia gravis, and this was subsequently confirmed. In 1934 Mary Walker,[4] acting on the analogy between the symptoms of curare poisoning and myasthenia gravis, found that injections of prostigmin had a remarkable if transient effect on the muscle weakness; patients with profound weakness of the eye, face, and limb muscles might become almost normal within half an hour of the injection, but the effects wore off within 3–4 hours When prostigmin was found to be effective by mouth, though the dose was considerably larger than by injection, a new era opened for the sufferers from this disease. In many patients, however, increasing doses had to be given, and in some the myasthenic symptoms were not properly controlled even by large doses. A new drug—di-isopropyl-fluorophosphate (DFP)—which inhibits cholinesterase activity has recently been introduced at the University of Pennsylvania In 6 cases of myasthenia gravis Comroe and his colleagues[5] found that the cholinesterase activity of the blood-serum was completely inhibited by oral or intramuscular administration of DFP, and there was some increase of muscle power; but the effects were notably less than with prostigmin, while larger doses of DFP caused nausea, vomiting, and faintness which were not adequately controlled by atropine. The main advantage of DFP is that its action lasts much longer than that of prostigmin, and a combination of the two drugs might at times be helpful in treatment. Work is being carried on with congeners of DFP in the hope of finding a more efficient drug. If we accept the view that there is a curare-like substance in the serum of myasthenic patients, it is possible that prostigmin is more effective than DFP because it has a direct action on this substance whereas DFP relies solely on its anti-esterase activity.

Surgery offers an alternative approach. It was an old observation that cases of myasthenia gravis sometimes showed tumours of the thymus at autopsy, and on this basis Blalock and others[6] in the United States, and Carson and Keynes[7] in England performed thymectomy for the treatment of the disease. In 1946 Keynes[8] reported on 63 patients treated by thymectomy; there were 9 deaths, but 7 of these had occurred in the first 21 cases and the postoperative mortality had become steadily less. Of 41 patients followed up for a reasonable time 14 were apparently cured, 15 so much improved that the dose of prostigmin needed was considerably reduced, 3 only slightly improved, and 9 not improved at all There is no doubt that thymectomy is a real advance in treatment, especially in the younger patients with a relatively short history. In Paris a new surgical treatment has recently been introduced—bilateral denervation of the carotid sinus. Suprarenal cortical extracts have been thought to improve the symptoms of myasthenia, and this operation is supposed to cause hyperplasia of the suprarenal cortex. Thévenard and Leger[9] have operated on one case of severe myasthenia with respiratory crises. Improvement started within two days after the right sinus had been denervated, and the patient was normal within four months; she relapsed shortly after that, but after denervation of the left sinus she again improved and two years later was said to be practically normal though still taking small doses of prostigmin. This appears to be the only case so far treated by this method, and in such a fluctuating disease little can be deduced from the results in one case. Indeed, the absence of a careful follow-up of a large series before the introduction of prostigmin makes it difficult to assess the results of any new treatment.

Though still cramped through bomb damage and continued hospitality to other bodies, and hindered by staff shortage, the London School of Hygiene and Tropical Medicine lost no time at the war's end in setting itself to restore and surpass pre-war standards. The report for 1945–46 records that teaching for the D.P.H. was resumed in the late summer of 1945, with a duplicate course for 39 further candidates beginning in April, 1946; and other departments were almost as quick off the mark. Among the year's developments were the formation of a new department of human nutrition and the creation of a chair of clinical tropical medicine; plans for a department of occupational hygiene have been approved.

Annotations

CONVALESCENT HOMES

THERE is still doubt (and some anxiety) about the position of convalescent homes in the National Health Service. Will the Minister of Health take them over on the appointed day, like hospitals; or will they be allowed to continue as independent units, perhaps under some form of central supervision? These homes are mostly small and often highly individual. Good food, fresh air, and a care-free atmosphere are their therapeutic weapons, and there is a feeling that while the State can supply the first, and nature the second, only institutions possessing complete freedom of action can supply the third. The fate of these homes will probably have to be decided on their merits, the regional boards being responsible for settling the degree of liberty to be accorded to each.

Meanwhile the surprising fact remains that no-one knows where all the convalescent homes are nor what they do. For the London area King Edward's Hospital Fund has set up a committee, with Sir Henry Tidy as chairman and Mr. O. N. Chadwyck-Healey as vice-chairman, which is now at work trying to make a comprehensive list of homes. The task of finding and visiting these has mainly been undertaken by members of the Institute of Almoners, who have already recorded details of about 150. The results of their labours will shortly be published in the form of a directory of convalescent homes, which should be assured of a welcome from doctors as well as hospital authorities. The committee also hope to increase the number of convalescent beds, which are urgently required, by giving financial and technical assistance to homes which need help. Many homes which are already open and active have asked for the committee's aid to expand or improve their work. But another group which require help still more are the dormant homes—those which closed during the war and have not yet reopened. Unfortunately the most popular area for convalescent homes in England is along the south-east coast, and since this was particularly exposed to enemy attack during the war very many had to close. To find out what has happened to these, and to encourage them to reopen, is an onerous but useful task. It is to be hoped that the committee will be able to restore a substantial proportion to the active list.

ELECTRICAL PROPERTIES OF TRYPANOSOMES

A NEW approach to some of the puzzles of African sleeping sickness and the allied trypanosomiases is offered by Fairbairn and Culwick,[1] on the basis of many years' experimental and field work at the Tinde Laboratory in Tanganyika. Broom and Brown[2] showed ten years ago that 72 hours after infection of a tsetse fly with one of the polymorphic trypanosomes, *Trypanosoma gambiense*, *T. rhodesiense*, or *T. brucei*, the parasites in the gut of the fly all carry a negative electric charge. When the parasites invade the salivary glands of the fly their charge is reversed. Fairbairn found that after infection of a rat with salivary-gland forms of *T. rhodesiense* the trypanosomes are at first predominantly positively charged; as the infection progresses the proportion of positively and negatively charged parasites fluctuates widely.

Fairbairn and Culwick[1] now believe that much that is known of the polymorphic trypanosomes can be explained on the assumption that the electric charges they carry greatly influence their behaviour, that the parasites obey the laws governing charged bodies, and that their heterogeneous properties are maintained by syngamy in nature. Examination of stained dried thin film preparations of blood was found to afford a simple and accurate means of determining the electrical charges carried by *T. rhodesiense*. Positively charged parasites are seen in contact with the red cells, which carry a negative charge; but negatively charged parasites are repelled by the red cells, and the red cells in close proximity to such parasites are deformed. There are long slender, short stumpy, and intermediate types of each electrically charged variant, the negatively charged being significantly shorter than the corresponding positively charged. The maintenance of strains for long periods by syringe passage in animals alters their virulence and their electrical, chemical, morphological, and developmental characters. Syngamy would tend to perpetuate heterogeneity of the parasites; but artificial conditions of maintenance and transmission would lead to genetic segregation. Syngamy was actually observed between trypanosomes carrying opposite charges, but not between negatively charged or between positively charged parasites. It was found that a trypanosome of any form—long, intermediate, or short—will fuse with another of the same or different form, provided it is of opposite charge. The long forms multiply freely by binary fission; but the intermediate and short forms do not readily do so; they result from syngamy of long forms and develop into long forms with or without further syngamy.

ALIVE, ALIVE-O

OYSTERS, of which Sam Weller noted the "very remarkable circumstance—that poverty and oysters always seems to go together," have grown exclusive with the years, and are nowadays as scarce as formerly they were abundant. The reasons have been set out[1] by Mr. H. P. Sherwood, senior naturalist to the Ministry of Agriculture and Fisheries, who also considers mussels, cockles, escallops, and "queens" (all of which, like the oyster, feed by filtering particles out of the water passing through their gills), and whelks and periwinkles (which, on the other hand, are browsers). Our grandparents, it seems, devoured oysters so freely that breeding stocks fell and prices rose. Despite various Acts and orders our oyster beds have never recovered from these depredations, and moreover have been thinned still further by periodical hard winters, and by pests invading the beds. The output of native oysters fell from 38 million in 1920 to less than 7 million in 1930, stocks having been depleted by a heavy mortality in 1920–21. The average yearly output from 1924 to 1938 was 12½ million.

Yet even if oysters could abound as they did in the past, their reputation for carrying intestinal infection, including typhoid, would probably hinder a wide return to popularity. They are more liable to become polluted nowadays, because, during the last century, local authorities of towns near the sea began to dispose of water-carried sewage by discharging it untreated on foreshores or estuaries. Sewage is generally released after half-ebb, and runs through comparatively narrow channels, many of which contain oyster or mussel beds. The filtering capacity of these creatures is such that a single mussel in a day clears over 10 gallons of water of all suspended particles, including bacteria; so shellfish taken towards the end of the ebb are likely to be heavily polluted. Fortunately they have an equal capacity for cleansing themselves, given the chance; and it is with methods of providing such chances that Mr. Sherwood is chiefly concerned.

Disorders due to shellfish include typhoid and paratyphoid, and milder intestinal infections associated with

diarrhœa and vomiting; bacterial food-poisoning from stale shellfish; a rare type of paralytic poisoning acquired by eating shellfish which have been feeding on dinoflagellates (small poisonous organisms); and allergic symptoms, usually urticaria. This last can only be avoided, in susceptible people, by excluding shellfish from the diet; but the first three can be prevented if the shellfish are purified before they are sold and eaten.

The ceremony of purification, though simple, is based on careful experiment. The shellfish, spread about two deep on wooden grids in large tanks, are thoroughly hosed with a strong jet of water to remove external mud, and the mud is sluiced away. The tank is filled with purified sea-water, and the shellfish are left in it overnight. Their excreta fall to the floor of the tank, and the water soon becomes glass-clear. Next morning the tank is drained, the fish are hosed, and the waste matter is sluiced from the tank, which is refilled again, and again left overnight. Next morning the bath is drained and flushed again and the shellfish are once more hosed; they are then left covered for an hour in sea-water containing a trace of chlorine (3 parts per million), in which they remain closed, and which sterilises the outside of the shells. They are packed in bags or containers sterilised in chlorine, and sent to market.

Purification stations have been set up at Conway, at Lytham, and at Killorglin, Cromane, in south-west Ireland. Results have been good; at Conway, for example, cases of typhoid due to infected mussels, formerly common, are no longer reported, and Lytham mussels and Brightlingsea oysters have proved equally innocent. Mr. Sherwood thinks that confidence in the method is justified because the shellfish visibly discharge their contents, and the rectums of any examined are seen to be free from fæces; moreover, bacteriological tests show that sewage organisms are greatly reduced, though it is not claimed that they are removed outright. Whelks and winkles, being eaten after cooking, are always reasonably safe, but Mr. Sherwood considers that, thanks to improved conditions, "shellfish in general can now be eaten with greater confidence."

COLOUR-BLINDNESS

THE colour-blind are often unaware of their disability. This is partly because, as children, they learn to name colours by association: the grass is green, the sky blue, the pillar-box red, and so on. But it is also because they become skilled at using such clues as texture and brightness—yellow, for instance, appears brighter than red or green under the same illumination. This unawareness may give rise to difficulty and disappointment. A lad who has specialised in his later school years with the aim of entering the Navy or R.A.F. may be rejected when the entrance medical examination reveals for the first time that he is colour-blind. The committee set up by the colour group of the Physical Society[1] to consider defective colour-vision in industry quotes the case of the draper's assistant who startled customers by the ties and socks he offered in response to requests for definite colours. On another occasion a controversy arose through the inability of a colour-blind geologist to read a colleague's coloured maps.

In occupations where defective colour-vision might lead to disaster, all would-be entrants are tested. One of the classical tests, Holmgren's wools, was designed after a railway accident from this cause. In industries such as colour-printing and photography employers sometimes insist on testing entrants. But there is no preliminary test for many of the occupations demanding accurate colour-vision: these range from textile weaving to horticulture, in which the colour-defective may find difficulty in deciding when fruit and tomatoes are ripe for picking. In these jobs the defective becomes slow and inefficient, often without recognising the real cause.

Colour-blindness is not uncommon, being found in various forms in about 8% of males. Usually, like hæmophilia, it is inherited by male children from their mothers. In the female it is rare, occurring only in children born of a colour-blind father and a mother who is a carrier. There are all degrees of disability, the most usual being difficulty in distinguishing between red, green, and yellow.

The committee holds that all whose colour-vision is not normal should be made aware of it, and should know how far the disability is likely to affect their careers. Colour-vision is already examined during prevocational testing in parts of Scotland, notably Edinburgh and Glasgow. Most of those employed in industry, however, go to work direct from school, and the committee recommends that the test should be made on all school-children—or at any rate all boys—at the age of about 13. It is suggested that one of the confusion chart tests, such as Ishihara's, could be modified so that a whole class could be tested simultaneously; those who failed could be examined individually. The tests need not be conducted by a doctor. An experiment in which the Ishihara charts were thrown on a screen by an epidiascope showed that the group-testing of colour-vision is feasible. Whether the addition of yet another non-educational activity to the school curriculum is desirable is another matter.

THE COST OF LIVING

THE plaintive note struck by one of our correspondents recently on what a contemporary unkindly labelled "The Doctor's Dilemma—or how to live on £1000 a year" gives point to the current discussions on the cost-of-living index. No doctor struggling with his personal budget is likely to be reassured by bland statements to the effect that the cost of living as measured by the present index has risen by only a third since 1939. Wage levels alone have risen by two-thirds, and this rise is reflected in the cost of most articles now for sale. In fact, the present index is admittedly so manifestly out of date that the Minister of Labour and National Service has adopted the recommendations of his committee[1] for an interim index "to provide a measure for the time being, of future changes in the retail prices of the things in which ordinary working-class households are interested." The present index, based on the purchases made by a sample of labourers' families before the first world war includes articles such as tallow candles which are unlikely (except perhaps during the half-light of the morning power-cut) to be of much interest to the modern housewife. Designed as it was to show the average percentage increase in the cost of maintaining unchanged the standard of living of a selected group of families at a fixed date, it takes no account of the changing patterns of purchasing habits demanded by the rise in the standard of living in between the wars. For example, in recent years demobilisation and the setting up of many new homes has increased the proportion of purchases of household goods compared with other items such as apparel and food.

To make the index a reasonable overall guide to the cost of the total purchases being made at any one time by the working-class population, the actual retail costs must be multiplied or "weighted" by factors proportional to their relative importance. Thus at the present time, household goods would be heavily weighted to indicate that so many men had to buy this type of merchandise. Conversely, the cost of tallow candles, having an insignificant weighting, would be negligible in the summation of all items to form the final index. The committee therefore suggests that sample inquiries into current purchasing habits should be made from time to time to ascertain the weighting indicative of the relative importance of the various items of expenditure whether essential or recreational. The first index calculated under this new régime will form the base-line of 100 against which future changes will be measured. There is to be no attempt at comparison with a pre-war standard. All this, of course, will take time, and as a temporary measure an index based on a 1937–38 survey of working-class budgets will be used. The increased weighting of rent, rates, and many "non-essentials" not previously included, and the decrease in the weighting of food which this entails, will make for a more realistic measure of the cost of modern working-class purchases.

[1] H.M.S.O. Cmd. 7077. Ministry of Labour and National Service: Interim Report of the Cost of Living Advisory Committee.

The economic questions involved are very complex. Food subsidies have kept the level of the present index, to which the wage scales of $2^1/_2$ million workers are related by agreements, within reasonable limits. Any increase in the index, either by reduced subsidies or by the new method of compilation, may bring fresh demands for higher wages and accelerate the upward spiral of inflation. As the *Times* remarks, "the interrelation of wage-rates, cost-of-living index and subsidies constitutes an impasse which must somehow be circumvented." This will inevitably influence the consideration of the terms of professional remuneration shortly to be negotiated.

EDUCATION FOR MEDICINE

It is always possible to learn from the difficulties of others, but where the problems are almost identical with our own a sense of comradeship is roused which bridges oceans and denies distance. In America, the Committee on Medicine and the Changing Order, established by the council of the New York Academy of Medicine, is reviewing educational method as applied to medicine, and under the ægis of this body Dr. Raymond B. Allen, from his wide experience as an educator, has made an analytical survey of the problems of American medical education,[1] much of which might well have been written about our own system.

Dr. Allen justly holds that the foundations of a medical career are laid in the early general education of the child. He points to the danger of dulling those bright facets of the child's untutored mind—"the natural curiosity and imagination" without which "there can be no lasting educational influence or progress"—by the imposition of a traditional educational system planned by adults. These inherent qualities of the child's mind are the mainspring of its future career; if they are congenitally absent or are destroyed by misuse, they cannot be replaced, and they must at all times be exercised by the challenge of appropriate studies. Outlining the programme of a liberal education which in this case happens to lead on to a medical career, but which might equally well culminate in any of the learned professions, Dr. Allen shows a breadth of outlook which makes his book worthy of study not only by deans of medical schools but by all who are concerned in child and adolescent education. Admittedly he looks to the ideal; and it is likely that the prevailing error of teaching too much in detail and too little in principle will defeat his aims.

It is clear that he deeply distrusts that early and enforced specialisation which, both in the United States and here, compels a disastrous narrowness of adolescent education at the most formative age. He comments upon the illiteracy of American students, and feels their lack of facility in oral and written communication "is a serious indictment of both secondary and collegiate education." He stresses the apparent lack of first-class brains among the student entry to the medical schools, which results in the padding-out of the schools and later of the profession with second-rate men, who though technically efficient lack the wisdom and the approach which endow each case of illness with a humanising intimacy linked with the individuality of a research investigation. Faintly but definitely he scents from afar the possibility, even in America, of a State medical service born of the inequality in the distribution of medical facilities to the poorer and the less populous districts. He suggests that this may not be purely a problem of money, but may be due in part to the training of students in hospitals armed with a profusion of specialised ancillary services; for after qualification the young physician may feel driven to live in an area where such services are freely available—not having been trained to manage without them.

For the future, Dr. Allen foresees a gradual reduction of specialists as rising standards of living and broad therapeutic advances, such as the bacteriostatic drugs, eliminate the difficult techniques upon which such specialism depends. Then the doctor will become the priest of good health: "the physician as a highly educated citizen shares responsibility with other community leaders in the endeavour to create the conditions which will improve the general economic and social well-being of the people as a whole." He asks, "Does medical education share in the responsibility for the failure of the medical professions to exhibit social insight and aggressive leadership in molding public opinion towards a comprehensive handling of the problem of adequate medical care for all the people? The answer is undoubtedly yes."

Many questions will stir in the reader's mind. Are we spoiling the child mind by traditional and inelastic methods of education? Is the occasional brilliant brain merely the one which is tough enough to survive a faulty educational system? Is that system sufficiently at fault to require, not patchwork revision from time to time, but radical reconstruction from an entirely fresh outlook? "It is the responsibility of education," writes Dr. Allen, "to keep pace with the times if, indeed, it cannot set the pace."

BETTER CARE FOR THE HOMELESS CHILD

THE Government have accepted the main recommendations of the Curtis and Clyde Committees, and have decided to make the Home Office the central department responsible for the care of homeless children in England and Wales. It will be remembered that the Curtis Committee wished to see supervision of these children brought under a single department, though they did not want that department to be responsible for every aspect of their lives. Thus the Ministry of Education should, it was felt, have the same responsibilities for educating them as it has for children living with their parents, and the Ministry of Health should have similar charge of their health. The supervising department was in fact to become a sort of father-figure to the children, and should have a children's branch which would make a study "of child welfare on the side of the home," and an inspectorate capable of considering the child's total welfare as a person.

These principles have been fully accepted by the Government. The Home Office is to have a new and enlarged children's branch and an expanded inspectorate; similar functions will be assumed by the Scottish Home

Department. A standing advisory committee containing representatives of the Ministries of Health, Education, and Pensions will support the Home Office in its new task. It has always been responsible for children in any voluntary homes not inspected by other departments and for children boarded out with foster-parents by juvenile courts; it will now take over, from the Ministry of Health, children whom public-assistance authorities have placed or boarded out in local-authority institutions or voluntary homes. One duty will be to make more good foster-homes available; and we share the Prime Minister's hope that an increasing number of people in comfortable circumstances will take children into their homes.

The most important recommendation of the Curtis Committee—that every local authority should appoint a children's officer—has also been adopted. These careful plans for homeless children are welcome; and should be explained simply to the children themselves. The knowledge that their country feels serious concern for their welfare should help to give them the security they so much need.

PROGNOSIS IN ERYTHROBLASTOSIS FŒTALIS

LAST year Wallerstein[1] reported 3 cases of severe erythroblastosis successfully treated by removal of the blood of the newborn infant and its replacement with Rh-negative blood. He has now published[2] 7 successful cases, 5 of them having a severe icterus gravis. (The protocols of the other 2 cases are not sufficient to make this diagnosis certain.) There were 2 failures in infants suffering from icterus gravis treated after the 48th and the 60th hour, and it is suggested that these might have been saved if the treatment had been instituted during the first 24 hours of life.

Wallerstein's original technique was to remove the infant's own blood by fontanelle puncture of the longitudinal sinus and to transfuse Rh-negative blood into a cannulated arm vein. He infused 75–100 c.cm. more blood than had been removed. Wiener and Wexler[3] have found that, by heparinising the infant with 500 units intravenously and cannulating the cut radial artery, they could remove through a 20-gauge needle 150 c.cm. of blood before clotting occurred in the radial cannula; by giving a further 500 units of heparin it was possible to remove a total of 400 c.cm. Wiener[4] has described 2 successful exchange transfusions in infants with icterus gravis, and promises a report on 17 infants with only 1 failure.

The procedure is readily practicable and satisfactory when the diagnosis is made early, and offers many advantages over simple transfusion with Rh-negative blood. It is still too early, however, to be certain that it offers a better prognosis. The early reports[5] suggested that the prognosis could be dramatically improved by transfusion with Rh-negative blood, but this view has not been generally confirmed. The general impression of pædiatricians is that the mortality from this disease is still around 50% and that in the infants who survive damage to brain and liver may be manifested later.

The pathogenesis of icterus gravis and erythroblastosis fœtalis in general is still not fully understood. There is general agreement that in most cases of erythroblastosis fœtalis there is an Rh blood-group incompatibility between mother and fœtus, the mother being usually Rh-negative, with Rh antibodies in her serum, whereas the fœtus is Rh-positive. It is generally accepted also that the maternal Rh antibody, be it agglutinin or incomplete antibody or both, crosses the placenta and can there attack the fœtal red cells which contain the Rh antigen. Wiener[6] has postulated that the clinical type of affection of the infant depends on the type of maternal antibodies produced, so that the Rh iso-agglutinin in the mother leads to icterus gravis in the infant, whereas the incomplete or "blocking" Rh antibody in the mother causes congenital hæmolytic disease—that is, congenital anæmia or hydrops fœtalis. Wiener[7] has since produced statistical evidence in favour of this conception. In 25 instances where the mother's Rh antibody was the iso-agglutinin there were 2 stillbirths, 7 cases of hæmolytic anæmia, and 16 cases of icterus gravis. In 57 instances where the maternal agglutinin was a "blocking" antibody there were 25 stillbirths, 24 cases of hæmolytic anæmia, and 8 cases of icterus gravis. In 15 instances where the maternal antibodies were both bivalent and univalent there were 4 stillbirths, 10 cases of hæmolytic anæmia, and 1 case of icterus gravis. It seems probable that, under the term hæmolytic anæmia, Wiener includes cases which would be called icterus gravis in this country. His figures—41 cases of hæmolytic anæmia to 25 of icterus gravis—are certainly vastly different from those met with here, where the diagnosis "icterus gravis" is many times more common than "hæmolytic anæmia," even when hydrops fœtalis is included under hæmolytic anæmia.

Both Wiener and Wallerstein, though they have made notable contributions to pædiatric practice by evolving this technique of exchange transfusions, may be raising unduly high hopes. First, the treatment must be given very early. Secondly, both appear to lay too great a stress on the damage to the infant in extra-uterine life. That damage also occurs in intra-uterine life is evidenced by the high proportion of stillbirths in cases of Rh blood-group incompatibility between mother and infant with maternal iso-immunisation. If the fœtal tissues contain the Rh antigen, as has been demonstrated by Boorman and Dodd,[8] the tissue cells as well as the red cells will be damaged by the maternal antibody. In the long run, therefore, the greatest promise will be held out by a régime which will prevent the maternal antibody from being formed or from passing across the placenta to damage the infant.

IF THE TRIBUNAL ACQUITS

IN one of the committee discussions on the Scottish National Health Service Bill, which were concluded in the House of Commons on March 20, Mr. J. S. C. Reid drew from Mr. G. Buchanan, an Under-Secretary of State, an assurance that where the disciplinary tribunal acquits a doctor accused of misdemeanour the Secretary of State will have no power to reverse the decision. From the proceedings in England Mr. Reid had understood that an appeal would be allowed in either direction, so that where a doctor was acquitted by the tribunal the Minister could then appeal to himself; and he quoted a remark by Mr. Bevan which certainly lent colour to this idea. In fact, however, the position in England and Scotland will be the same: if the tribunal condemns the doctor he can appeal to the Minister, but if it acquits him the acquittal is final.

Dr. Walter Ramsden, senior fellow of Pembroke College, Oxford, and professor emeritus of biochemistry in the University of Liverpool, died on March 26. In 1897 he qualified from Guy's Hospital, and he held the lectureship in chemical physiology in the University of Oxford till he took up his Liverpool chair in 1915. His most notable original work was on the chemistry of colloids. After his retirement in 1931 he returned to Oxford, where he continued his observations on adsorption phenomena and also on silk-fibrinogen.

SOCIAL MEDICINE

The Appeal of the Common Man

LORD HORDER'S ADDRESS IN NEW YORK

In an address to the Institute on Social Medicine of the New York Academy of Medicine on March 21, Lord Horder spoke of the new field now opening for the statesman, the sociologist, and the doctor—a field that *is common ground for all three.*

Although we have not been blind in the past to the sociological aspects of Medicine, he said, we have as yet done very little about it. I think the recognition of the *omission has gone far in the United Kingdom towards* deciding our statesmen that something *should* be done about it. Looking at our health services in a more objective way than the physician can possibly do they take note of this big gap that he himself is doing so little to fill. Then war, the great accelerator, has taken a hand by stressing the importance of "intelligence, agility, endurance, strength," and by giving the term "positive health" a more exact meaning. In short, "Social *Medicine . . . signalises . . . the birth of a new outlook on* human affairs, a new interpretation of human relations in a free society and a new scale of social values" (Crew).

But Virchow spoke of Medicine as a "social *science.*" *Can his use of the word "science" be justified in relation* to Medicine? I think it can and should. . . . But to make Medicine a complete science in the service of man we must arrange that it infiltrates this important and now more clearly perceived *sphere—as yet largely neglected—of* social need. This sphere lies between that in which the diseases of the individual patient are presented and treated by the individual doctor and the sphere in which the preservation of the public health is achieved by the proved methods of the State health officer. This largely untilled field includes all the environmental factors which influence the citizen's health and happiness—his conditions of work, his house and home life, his sense of *security or insecurity, and his ignorance of the things* that make for the salvation of his body and his mind. In short, as Professor Ryle has it, "our next advance" (in Medicine) "will be . . . concerned with causes" (as the last was) "but with the ultimate, rather than with the intimate, causes of disease."

OBSTACLES

As things are at present I do not feel at all hopeful that the physician is capable of dealing with this aspect of Medicine. I believe his incapacity to be due to two things —his lack of training for the particular job and his lack of time in which to do it.

The student's premedical *education is lopsided. Almost* from the moment the boy or girl has decided to become a doctor the confines of his or her interest tend to be more and more narrow. Medicine, which should have the widest contacts of any profession, almost ceases to be a "liberal" education, for its cultural outlook dwindles from this moment. . . . May I repeat something that I said about eight years ago?

> ". . . if it be advanced that the doctor's training has not, up to now, fitted him for work of this sort, then the sooner it does so fit him the better. Inevitably the doctor's work in the future will be more and more educational and less and less curative. More and more will he deal with the physiology and psychology of his patient, less and less with his pathology. He will spend his *time keeping the fit fit* rather than trying to make the unfit fit. And we must make it worth his while to do this work. This reorientation of his education, and of his work, is overdue, and it will remain overdue until reorientation occurs in the attitude of the health authorities towards *him and towards his sphere of* usefulness."

The other, and more serious, handicap to the physi in any effort he may want to make towards t *furtherance of "social trends" that* overlap so cl with Medicine, is his want of time. This, as I say, probably a more severe handicap than mere lack special preparation in this field. For, after all, the doct *is in the very midst of all that is happening to the* vario groups within the social fabric. He sees the peopl needs and his natural inclination is towards helping; it were not so he is unlikely to have chosen Medicine his vocation. But time is essential, and this he just hasn got. He hasn't got it because he is generally gros overworked and his day is badly organised. And it here, perhaps more than anywhere else, that the nee for developing our health services is so urgent.

When the statesman seeks to free the doctor fro trivialities and time wastage so that he may be able t pull his weight in the field of Social Medicine he deserve and must be given, all our sympathy and all our hel *But there are many of us in Britain who think that* th freedom should not be secured by nationalising Medicine because we consider that such a policy would lose t Medicine two of its most virile characteristics, which ar *individual initiative and the spirit of adventure.*

How, then, are we to free the doctor from his incessan grind and hurry? I think the Health Centre is th answer. The Health Centre could do much to organise doctor's work; it could also save him from the sterilisin effects of isolation. Moreover it could itself be a place where the social aspects of Medicine of which I have been speaking might be studied. . . .

MEDICINE MUST BROADEN

There are some 54,000 practitioners engaged in medical care in my country. There are nearly three times that number in yours. What is called the "impact" of *these skilled armies upon the public mind* is potentially tremendous. I have dealt with the doctor's influence in society in another place, saying of him that I thought he was the most important citizen the nation possesses. This sounds egregious seeing that I am a doctor myself But I believe the public takes the same view. *The physician* owes his power to three things—to his training, to his humanist outlook, and to his opportunity to effect a "close-up" with the individual patient. We must be insistent that the "close-up" should be *preserved* in any attempt to integrate our health services; it is a privilege that should be jealously guarded in the interest of the citizen and of medical progress.

But the scope of Medicine must broaden. There is today hardly a field of human endeavour that *does not* require the physician's advice at some time or other. In the words of Sigerist, "no longer a magician, priest, craftsman or cleric, he must be more than a mere scientist *Scientist and social worker, prepared to cooperate* in team-work and in close touch with the people he serves, a friend and a leader, he will direct all his efforts towards the prevention of disease and become a therapist when prevention has broken down—the social physician protecting the people and guiding them to a healthier and happier life."

The "all-in" war that has so recently swept like a blizzard across our social fabric at home has shaken us rudely, physicians *included, out of a number* of our former complacencies. A few of us grouse because a lot of the things we have to do seem trivial, detached, or beneath our dignity. We can't any more do only the things we like doing most, nor only the things we think we can do best. And *I am not at all* sure that we *will* ever have the same choice of doing things that we previously had, or that it is good that we should. And therefore I consider that to yield in this matter is an ignoble attitude. I would prefer to think that we orientate willingly and actively towards the general *social scheme. The doctor's* job has, by its nature and traditions, always been linked up closely with the special structure of the day; only in quite recent times does the doctor seem to have been aloof from the rapidly changing pattern that has disclosed itself.

When I use the phrase "general social scheme" I do not mean yet another plan; I mean, pragmatically, things as they are at this moment in the unbroken stream of human welfare; and of course I have in mind also the probable continued trend of things in the future.

I want to see a "close-up"—or it would be more accurate to say a "closer-up"—between the physician and the social services. Is the physician—and when I say physician in this connexion I mean the family physician, than which I can give him no better or more significant title—is the physician going to continue only to cure or relieve disease, or is he going to make contact with this health business that we are finding to be such a vital national asset? This rigid distinction between the G.P. and the S.H.O. (State health officer), and, alas! the antipathy so often seen between them, are surely due to a misconception on both sides as to what the medicine man's function really is; he was the "health man" to the tribe, and he should be still, and only, that, to the men and women of today.

We all pay lip service to the great importance of preventive medicine. But again and again we say "that is the State health officer's job," when really it is every doctor's job. To do the G.P. justice, he does make many contributions to preventive medicine that are not recognised as such, but they *should* be recognised and it is the business of the State to recognise them. Inevitably, if the G.P. does not accept the challenge of this position, and is not helped by all of us to accept it, the S.H.O. service will expand whilst that of the G.P. contracts and there will then be intensified that rivalry between private and public medicine which we all of us surely deplore.

I want to see the physician not only make use of the public-health services, but show some passionate conviction about them in his patient's interest. Take school meals as one example: if the physician is only doctrinaire on the matter, and not intensely practical, Mrs. Jones isn't stimulated and the local education authority doesn't get busy.

THE BASIC NEEDS

Take the case of industry. Work is good; work is health-giving. But it is the doctor's duty to protect the worker against excess fatigue, against dullness, and against the various hazards of his job. In all these matters Medicine has accumulated a mass of facts, but they are very largely wasted because they are not implemented in terms of social service. If I embarked upon the subject of Nutrition, and the light which our rapidly growing knowledge in regard to it has thrown upon food, I could, of course, give equally striking examples of the need for the physician's direction and execution. To say the truth, there is very little in the life of John Citizen, whether he be in a factory, an office, or a public-utility service, that does not give the physician scope for the practice of Social Medicine.

Consider the basic needs of the citizen—I have long ago stated and re-stated them:

1. Sufficient of the proper food.
2. Suitable shelter and clothing.
3. A satisfactory job of work.
4. Access to the fresh air and sun.
5. Reasonable leisure and the amenities of life.

In every one of these the doctor must stake out his claim, for in every one of them his is the knowledge that should guide and it is his enthusiasm that can stimulate to achievement. It is not as mere passengers that we physicians must take our part in these affairs. We must lead; we must guide the politicians since they cannot act effectively without expert help, and we must keep the citizen's end up, since he learns to rely upon us for this.

But suppose the politician won't be guided? Suppose it is as Swift wrote in a letter to Pope: "Although I have known many great Ministers ready enough to hear opinions," said Swift, "yet I have hardly seen one that would ever descend to take Advice; and this pedantry ariseth from a maxim which they themselves do not believe at the same time they practice it, that there is something profound in politicks, which men of plain honest sense cannot arrive to." In that case the physician has no alternative but to appeal to public opinion, continuing to serve his patient in the manner which he believes to be in the patient's best interest. . . .

THE FUTURE

If, finally, any one of you should ask me, point-blank: "Do you see hope in the future of Medicine?" I should reply: "Yes—I see more hope for ourselves as doctors and for the people who will come under our care, in the future of Medicine than perhaps in any other single thing in the new world towards which we are hacking our way. We at least have not—yet—forfeited the trust of people for whom we work; we at least have not—yet—turned inwards in despair, bartering our spirit of adventure for a mere hope of security. We stand for sane knowledge, selflessness, and mercy in a world gone mad. We cannot let these people down who trust our profession, and it is in this firm resolve that we shall face the future of Medicine."

A MEDICAL SERVICE FOR STUDENTS

FROM OUR EDINBURGH CORRESPONDENT

For the past 17 years students at Edinburgh University have been entitled to free medical examination at entry and at other times as they wish; they have also been encouraged to engage in physical education. Domiciliary treatment, though sometimes arranged unofficially, has hitherto not been organised by the university.

Lately the service has been extended, and every new student is now advised to avail himself of the chance of free clinical examination and chest radiography. During the present academic year 752 (about 60%) of the male students have taken advantage of the scheme; and the proportion of women is about the same. Amongst the men pulmonary tuberculosis was disclosed in 8, all of whom had been unaware of it.

Besides routine medical examinations, consultations are now held three days a week for students wanting advice; and any student unfit to attend may obtain free domiciliary treatment. The medical service works in liaison with the department of students' social service, the director of which makes a point of getting into touch with the parents of sick students. The service has been devised for the benefit of those whose homes are not in Edinburgh; and local students are encouraged to seek the advice of their family doctor rather than call upon the university medical service. The Royal Infirmary has for many years provided a separate students' ward, which is still used to the full. A dental service, organised through the Dental Hospital, is already in existence.

Discussions which are now being held will, it is hoped, eventually result in the establishment of a university "sick bay" or "sick dormitory" in one of the university hostels; and a scheme for the full care of students with tuberculosis is also being considered. The physicians operating the medical service hope to obtain useful data on students' health and on their physical and psychological reactions to environmental circumstances.

"... No-one can foresee the basic discoveries of tomorrow; the predictable belongs to the level of applied research. At best we can merely select phenomena which we do not understand, confident that if we investigate them in a true scientific spirit, some useful knowledge will emerge."—Dr. JAMES CRAIGIE, F.R.S., in his presidential address to the Society of American Bacteriologists. *Bact. Rev.* 1946, **10**, 73.

Reconstruction

"THE SYLLABUS"

FROM A CORRESPONDENT

THE General Nursing Council has been considering the "improvement" (by elaboration and addition) of the syllabus to be covered in preparation for the State examinations for nurses. The Royal College of Nursing, full of zeal for the development of "nursing education," has announced an optimistic scheme for setting up a University School of Nursing. Mr. David Patey, F.R.C.S., in the *Times* of March 7, challenges the council of the college on the results of American experiments in making nursing a university subject, as compared with the results of the British system of nurse training. Both he and *The Lancet*[1] quotes the opinion of an American surgeon who says that under the programme of advanced nursing education in the United States, the nurse is not being trained primarily to care for the patient.

Thus we meet once again, in modern dress, the old controversy: *do nurses have "too much theory" nowadays*; does it matter how much or rather how little they know, as long as they have "nurses' hands" and do what they are told? Has actual bedside nursing deteriorated since the theoretical course became more exacting, and if so is it a case of propter hoc or only a case of post hoc? The conservative party in this debate (including many members of the medical profession) assumes a conflict between theory and practice: if the theory goes up, the nursing practice at the other end of the seesaw must inevitably go down. The "progressives," who include the most articulate portion of the nursing profession, might sometimes be thought (no doubt quite unjustly) to believe that if you take care of the theory, the practice will take care of itself. Truth, as is her wont, has eluded the earnest controversialists, and laughs at them unnoticed from a corner of her own.

The first responsibility of the nurse, as of the doctor, is the well-being of the patient. The physician's responsibility demands knowledge, judgment, reflection, clinical experience, and skill. The nurse's responsibility is less directive, but is more constantly and more intimately concerned with the patient's comfort and well-being in mind and body. The most important part of her teaching, therefore, should take place at the bedside, and it is there that she should develop the skills which are the real measure of her proficiency and success as a nurse. Where this does not happen, it may be because she is distracted by classroom work for which her educational background is inadequate and is worried by the prospect of examinations. But it is at least as likely to be because her time and energies are used up in a scramble of ward routines connected only very remotely (if at all) with the comfort and well-being of the individual patient, and because no-one in the wards has time or responsibility to teach her the true art of nursing. It is not the patient, and not always even the medical staff, whose well-being is most seriously disturbed if every piece of ward furniture and every flower-vase is not set to an unchanging pattern by 10 A.M. In the immediate shortage of domestic help, some admixture of domestic duties with nursing is inevitable, but there should be some system whereby the necessity for this is questioned at frequent intervals now that there may be a temptation to economise in the more highly paid domestic labour at the expense of the student nurse.

If the training of every nurse were centred in the wards and in the care of her patients as individuals, surely the classroom work could and should be allowed to vary in accordance with the capacity and educational background of the students or pupils which each training school can recruit. It is only common sense to that the nurse who is capable of grasping the p underlying the techniques she must follow in the will be the better for knowing them, and should taught them as part of her course, rather than being to find them out for herself from textbooks if she sufficient enterprise. As regards the more au nursing procedures, there is real danger in pra training which is so stereotyped and so unrelated to principles that the nurse cannot adapt her practice safely to varying conditions. Recent developments in medical treatment could provide many instances of the risk of leaving a nurse to follow instructions without k and understanding of the processes involved.

The moral? Neither a more advanced compulsory syllabus nor an arbitrary levelling down to the capacity of the girl whose education ceased at 14, but a greater variety in the content of the nursing course, to match the great range of educational standard of mental capacity. Freedom for training schools develop their course on the lines best fitted to the student body which they are able to recruit, and financial independence to enable them to let that course centre in bedside teaching on a planned curriculum, undisturbed by the labour requirements of the hospital. A periodical review of the more impersonal ward routines to see which can be eliminated or mechanised, so that the individual care of the patient may come first.

Can all this be fitted into the present machinery for State registration? If not, an examination of the results of the present system may suggest that it is not simply the syllabus which should be revised, but the whole concept of a rigid national standard imposed on a profession which surely needs at least as much diversity and flexibility in its training and qualification as any other.

"We must make arrangements which will attract well-educated women into a profession demanding all their powers, but will nevertheless permit any sensible girl to attain the title of nurse if she shows aptitude for the care of the sick.[1]" The planners of the National Health Service would do well to make this twofold objective a matter of urgency, remembering that numerically the nurses are the most important group within the team on which the operation of the National Health Service will depend.

Public Health

A City Replanned

Charles Hastings, who maintained that no physician could practise without a knowledge of his locality, studied the population trend of his native city of Worcester in the year 1834, attributing its rapid rise rather to the lowered death-rate and greater expectation of life than to an increase in the birth-rate.[1] He reviewed the occupational diseases of leather-workers, glovers, needle-pointers, and operatives in the china works, and noted associations between the incidence of fever and the periodic flooding of the river Severn. Hastings, who had advocated compulsory drainage and vaccination and who had railed at the Government for its indifference to medical research and for its encouragement of quackery, reviled his fellow citizens for allowing their city to develop haphazardly at the expense of parks and natural amenities. Over a century has passed and the country has now entered upon an age of planning such as would have delighted his heart.

The city council of Worcester is to be congratulated on having commissioned, on a high professional level, an economic and social survey[2]; it has been prepared by the commerce department of the University of Birmingham and covers not only the city, which now has a computed population of 51,686, but the surrounding country and towns for which it is the transport, marketing, and social-services centre. The survey is literally built up from rock bottom, and shows how industrial expansion may be discouraged by reason of low water-pressure from piped sources, especially on a Keuper marl elevation with poor natural supply.

---

[1] *Lancet*, March 15, p. 333.

[2] County Town. A Civic Survey for the Planning of Worcester. By Janet Glaisyer, T. Brennan, W Ritchie, and P Sargant Florence. London: J. Murray. Pp. 320. 21*s*.

The industries change with the years. Just as in the past the clothing and carpet industries declined, the glove trade is now on the wane, and many reasons are given to account for this. On the other hand, engineering industries have developed rapidly within recent years, while the city is fortunate, especially in times of depression, in possessing a balance of industries not dissimilar from those for England and Wales as a whole, although in general a relatively higher proportion of juveniles is employed. The surveyors show the need to dovetail industries with differing seasonal fluctuations, to splice declining with growing industries, and to mix stable industries with those subject to severe cyclical depressions. One valuable suggestion is that the city should provide blocks of playing-fields to be let to those small factories which cannot afford to maintain their own. For Worcester to fulfil its function as the medical centre of the west Midlands, improvement of the hospital facilities is essential. With only 36 maternity beds and a central clinic over-ripe for condemnation, the city is not well provided for: the outstanding needs are for a "health centre," a maternity hospital, and at the other extreme a crematorium.

In the past the doctors in the vicinity of Worcester have frequently looked to Birmingham for consultants, so that there is need for further decentralisation of medical specialist services towards Worcester, especially if the city is to increase in size and if Droitwich and Malvern are to play their part in the comprehensive medical rehabilitation service.

Better bus services, more attractive shops and hotels, improved facilities for adult education, and good recreational amenities, including public gardens and an up-to-date outdoor swimming pool, will all be needed if Worcester is to become, as the surveyors hope, a tourist centre. The city, which is so full of historic associations, has delightful architectural features and with little trouble the river frontage could be made attractive, although it is disastrous that circumstances should recently have necessitated the erection of a large ugly power-station on the riverside. Surely even at this late date something could be done to remedy this harm.

Infectious Disease in England and Wales

WEEK ENDED MARCH 22

Notifications.—Smallpox, 0; scarlet fever, 1362; whooping-cough, 2277; diphtheria, 212; paratyphoid, 0; typhoid, 1; measles (excluding rubella), 11,295; pneumonia (primary or influenzal), 1035; cerebrospinal fever, 114; poliomyelitis, 8; polioencephalitis, 1; encephalitis lethargica, 3; dysentery, 48; puerperal pyrexia, 169; ophthalmia neonatorum, 57. No case of cholera, plague, or typhus was notified during the week.

Smallpox.—Up to March 29 no further case was reported. The last reported case, as we said last week, was in a man admitted to Surrey County Isolation Hospital on March 21.

Deaths.—In 126 great towns there were no deaths from enteric fever or scarlet fever, 3 (0) from diphtheria, 8 (1) from measles, 24 (5) from whooping-cough, 76 (13) from diarrhœa and enteritis under two years, and 66 (9) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 272 (corresponding to a rate of 25 per thousand total births), including 28 in London.

Planned Psychiatric Service.—The memorandum reviewed under this heading in our last issue (p. 421) is an appendix to a report on the planning of hospital services in the Berks, Bucks, and Oxon region, which is obtainable from the Nuffield Provincial Hospitals Trust, 16, King Edward Street, Oxford.

In England Now

A Running Commentary by Peripatetic Correspondents

I WISH newly qualified men would do six months general practice first and house-jobs afterwards. Don't tell me they learn confidence in themselves in hospital. There is no training for a G.P. like general practice. No big white chief comes round in the morning to check our diagnoses and treatment: No nurses stand straining at the leash for our commands. And the G.P.-turned-houseman would at least answer the telephone. Compare this with the present commonplace state of affairs—the sluggish, laconic young houseman answering an emergency call after 30–40 minutes, blissfully unaware that the G.P. at the other end has three more calls and is gnashing his toothless gums in frozen fury in a distant telephone booth.

* * *

As all good peripatetic correspondents should, I have been on tour. The trip did not carry my feet very far, but my mind has been forced out of the ruts that encompass it more closely every day. The traditional impossibility of getting away having been proved a downright lie, one wonders whether it was worth the trouble. It is pleasant to see old friends after the lapse of years, but it is of inestimable value to hear about their work. Medical thought, before it reaches the stage of print, is a local thing that can be snared only in its own lair. My friends were very generous, so my mind is stocked with a hundred new ideas. It is only by going the rounds that one realises how much local variation there is in hospital administration. The problems, in general, are the same throughout the country, but the solutions are the fruit of local action, local prejudice, and local competence—an example of the survival of the fittest in a field of infinite variation. I was even fortunate in finding a hairdresser who "never talked politics to gentlemen in the chair" and then condemned the whole Government in one sentence repeated in different terms with a twitch at my hair each time by way of emphasis. Finally, my mind replete, a kind friend found for my stomach a draught of nectar. So it was well worth while and I hope the all-seeing State will make a monthly "swan" one of its compulsory sessions for those of us who live in isolation. Perhaps it is too much to expect the nectar as well.

* * *

She was a multipara and well on in the second stage when I arrived. "No, Doctor," she said, "I haven't any rubber sheeting or thick brown paper. You'll have to use newspapers." A few moments later the baby was shot out on to a sodden copy of the *Daily Express.* This adhered lovingly to the child, and when the mother asked to see her latest I felt like a fishmonger displaying sixpenn'orth of cod.

* * *

The howlers which Dr. Firth quoted in his letter of March 22 are of course as nothing compared with the sort of answers one gets in the examination papers of native nursing assistants in South Africa. Their examination follows only 6 months' instruction, and they have a serious language difficulty to grapple with. Take these, for example: "After severe sweating the patient falls into a comet." "Our best source of mineral salts is Popular Pop." "The temperature is taken from him when he is warm. After that send the temperature to the doctor so that he may know what goes on and what comes back." "The nasopharynx has openings to the station." But this might be hung over the mantelpiece of every nurses' home: "Only for fire or bleeding must a nurse hurry, otherwise she must stroll." My reaction to these was Dr. Firth's second one: admiration for a gallant, if ineffectual, effort of memory.

Cautionary Tale

This is the fable of the two rectors' daughters. In the land of Albion were two villages so far apart that in each they did not know what happened in the other; though when matters arose in both that had a similarity the one to the other they were known in the great city in between. Hence this fable. In each village there was an elderly rector who had married late in life, and to his ageing wife one girl child had been born who at the time of the story was growing up. And in each village was a doctor who for four years had had no holiday—not for a single day—because Albion had been at war, and both of them had decided on a break and had employed a young locum tenens back from the war.

Now one of these young men had been trained at St. Didymus's Hospital. He was a graduate of an ancient monastic university and had taken a fellowship, and he was a very brilliant young man. He was called to the rectory because the daughter had a soreness of the throat; and he looked at it and said, "I think this is syphilis: we must have a Wassermann." Neither the rector nor his wife knew what syphilis was or who Wassermann had been. But they learnt later, after they had told all the village. The report came back negative; but the old man with his grey hairs went down with sorrow to the grave because it had even been suggested that his daughter could suffer from such a disease. Before that he complained to the doctor, who came back from his holiday and sent away the young man with a very bad chit to *the agency so that they would not employ him* again, and he could get no work, and took to drink, and finally breakfasted on gin on the seashore of a distant island, and there he died.

To the other practice went a Fawkes' man who was only an L.S.A. and he also was called to the rectory because the rector's daughter had a sore throat. She was a demure and silent little maiden, and he looked at her throat and wondered what it was. Now he was an early riser, and there had been some rain in the night, and as he had walked round the garden he had seen on the wall a slimy track where a snail had climbed. The track came back into his mind as he looked at that throat. So he asked the rector's wife to arrange for her daughter to strip to the waist that he might examine her chest. And as he listened to her lungs he looked at the skin of her chest, but it was without blemish. Then he took her by the hand with one of his own and bent her elbow, and with a finger of the other hand felt above the internal condyle on the arm. He felt a lymph-node on either side; and he wondered how he could get a blood-test without the old folks knowing. He dried his hands and went back into the drawing-room and told the rector and his wife that their daughter was suffering from a blood-poisoning and he must give her a tonic. And he turned to the girl and said, "It will be ready for you at 4 o'clock today; perhaps you will fetch it yourself?" and as he spoke he looked pointedly at her. When she came he asked her whether she knew what "syphilis" meant, and she answered, "Good God! It isn't that, is it? It must have been that blighter Bill. But how could that be? He rejoined his ship three months ago." And the young locum tenens said, "That is just about the time it would be; but I cannot be certain without a blood-test"; and he drew blood from her arm and it was strongly positive. When he told the girl she said, "Mother and father must never know," and he asked her whether there was anyone else with whom she could go and stay. She said, "Yes, there's my Aunty Judy: she's a sportsman and lives at Brighton." So the young doctor went to the rectory and told the old couple that their daughter was not progressing and he feared she might go into a decline and he thought she needed bracing air such as that of Dr. Brighton. And the rector said, "Well, there's Judy. She would have her. She's coming on Friday to stay the week-end"; and on Saturday he saw Aunt Judy and fixed things up, and he wrote to a friend in Brighton. From time to time for the next four years the rector's daughter went and stayed with her Aunt Judy and was cured of her blood-poisoning, nor did she go into a decline. And the young man from Fawkes' Hospital, who was only an L.S.A., pleased the doctor when he returned after having had an extra week's holiday, and he made him his assistant. Then he took him into partnership, and he married the rector's daughter, who was quite a nice girl after all, and she bore him four healthy children and they lived happily for twenty years till he gave his life on a desert in another war.

Letters to the Editor

SERVICE MEDICINE

SIR,—I have always looked to your journal to pro a realistic and objective policy; but I cannot con that any real advantage would be gained from a me of the medical branches of the three Services. I not agree with you more than when you state, in y leading article of March 22, that "medicine must as an equal in the highest counsels of the Armed Forces but it is just because the sailor, soldier, and airman h to perform such diverse duties, and are therefore s different persons, that separate organisations are req to keep them in health and attend to their sicknesses.

Health is not merely a negative state characterised the absence of sickness, but is very definitely a posi state of well-being, which, in the case of Service perso must be planned and fought for by the executive medical officers as a team. In order to exercise greatest influence in this team-work the medical offi must be an officer first and a doctor second. No offi can be a "good" officer unless he has fully studied environment and duties demanded of his men and traditions of their Service. He must, therefore, be officer of *that Service who has been trained in its* req ments and has lived in its spirit—only then can he b to possess the knowledge and prestige to talk authority at the highest level.

You suggest, further, that we need a training sch for Service medical officers which will bear compa with that of the Americans; but even the Ameri have their flight surgeons!

No, Sir, such a training school for a gargantuan co bined medical service would not produce medical office any more capable of either maintaining or re-establishing the fighting efficiency of our individual sailor, soldier and airman, but would only create a fourth arm "Service doctors." Presumably this idea would appea to those of bureaucratic, totalitarian persuasion; bu not to those whose aim it is to render the most efficient and effective service to the individual members of th Armed Forces, and so to those Forces as a whole.

R.A.F. MEDICAL OFFICER.

SIR,—It is not without significance that the material for your leading article of March 22 is quite openly admitted to be a study of the medical organisation o only one of the Services; and therefore it is perhaps pertinent to ask whether this can be an impartial survey of the organisation of "the medical services of the Armed Forces," or whether "it is generally agreed that their organisation left much to be desired."

That your journal, which is to be congratulated on publishing such an impressive and impartial article on Exports and Agriculture in your issue of March 15, shou publish such a misleading, mischievous, and misinformed article on Service Medicine is greatly to be regretted. More particularly is this so at a stage in the evolution of a State medical service for the community in general when there is a real need for informed opinion on the efficiency of the organisation of some, if not all, of the existing State medical services.

NEC ASPERA TERRENT.

P.S.—It is of some interest that airmen rejoining the Royal Air Force as a result of the Government drive for recruitment to the Armed Forces have publicly stated that one of the greatest factors influencing their re-enlistment is the existence of "a first-class medical service."

SIR,—Your plea for unification of the medical servi of the Navy, Army, and Air Force under a single head will be supported by many ex-Service doctors, particularly those who have suffered from the parochial atmosphere and the backwardness of one of the smaller services, those who while working in combined hospitals have experienced the labour of complying with three different sets of medical regulations, and those who knew the acute local medical shortages or duplication of facilities, the frustration and lack of medical liaison between the Services which existed in all but the most important fronts during the war.

There are other grounds for suggesting unification. A combined service offering a temporary commission with possibilities of duties at sea, abroad, or on air tations would probably attract many more young doctors than could the three separate services between them, and the unwelcome conscription of these young men at a vital stage in their apprenticeship might then be unnecessary. Secondly, promotion would come to depend more on professional or administrative ability than on seniority, a tendency which could only lead to better standards of work. Thirdly, I submit, a member of a medical corps would, to the average man, be more welcome as a medical attendant than an officer of the Navy, Army, or Air Force.

Bristol. J. NAISH.

AMYLOID MACROGLOSSIA

SIR,—I read with interest the article by Dr. M. D. Baber (Feb. 8) and the subsequent discussion by Dr. Parkes Weber, and Dr. Smith and Dr. Cooke (March 15).

It is apparent to me that more attention should be paid to the reports of Askanazy [1] in 1904 and of Magnus-Levy [2] in 1931, which noted the relationship of atypical systemic amyloidosis to diffuse plasma-cell myelomatosis; indeed, Dr. Parkes Weber [3] himself as early as 1903 remarked upon this association. After examining many cases of atypical amyloidosis, Magnus-Levy emphasised the fairly frequent association of these two rare conditions. Repeated confirmation of this relationship has come from the United States (Moschcowitz [4]; Robertson and Brunsting [5]; Rosenblum and Kirchbaum [6]; et al.) One case recently under my own observation illustrated the relationship extremely well.

I understand from Dr. Baber's report that the skeleton and marrow were not examined histologically. I would make a plea that this relationship be borne in mind in all cases of atypical amyloidosis, and that future publications relating to the occurrence of either localised or generalised atypical amyloidosis should include a description of the state of the bone-marrow. I believe that if this were done the frequency of such phrases as "unknown ætiological factors" and "obscure ætiology" might be reduced.

J. H. FODDEN.

Department of Pathology, University of Liverpool.

STAMMERING

SIR,—May I correct a mistake in Dr. Stein's letter (March 15)? The Chinese word for stammering is *k'ou-chih* (using the Wade system of Romanisation), and the version which he gave, *kchi-ko*, must surely be a corruption of that, even allowing for Romanisation in the German manner, employed by Kussmaul.

I should like to comment on the contention that stammering does not occur in the Chinese because they have a monosyllabic language. It is not only that Colombat seized upon a little anecdote as valid scientific evidence, but both he and Kussmaul misunderstood the actual nature of Chinese language and speech.

While it is true that from a philological point of view Chinese is basically a monosyllabic language, yet I learn, in conversation with a philologist friend, Mr. D. C. Yu, that, from earliest times, borrowings from the Sanskrit and Persian have contributed in effect polysyllabic words to the language. These were frequently phonetic translations, each syllable of the word being rendered by a single ideograph, which by itself possessed no meaning. These polysyllabic words (made up of several ideographs each carrying a syllable) are however rare, though phonetic translations of words from western languages are nowadays quite common.

On the other hand, a great number of Chinese words are made up of two or three independent ideographs, each of which standing by itself has meaning (apart from carrying a sound). Thus the word *k'ou-chih* itself is bisyllabic: *k'ou* means mouth, *chih* means *eat*. It is obvious that *k'ou-chih* means something more than *k'ou* and *chih*, just as *wireless* means more than *wire* and *less*; the word is a unitary whole, and not merely the sum of its parts. This tendency to form new words by combining ideographs is a fundamental one in the language (it is not, technically, *agglutination*), so that in a very real sense the language is also polysyllabic. The habit of certain translators from the Chinese, who render Chinese words into, say, English, according to their component parts, is pardonable for the sake of literary effect, but is psychologically false.

There is no reason to suppose then that Kussmaul's hypothetical "centre for integrating syllables" in speech is less exercised by Chinese than by any other (polysyllabic) language. Indeed it must be obvious to all who speak Chinese that words of several syllables exist, and it does not require acquaintance with the concept of organic integration in modern biology and psychology to realise that a work formed by two or more others is something on a level by itself, not explained entirely by its components.

That Kussmaul did not apprehend this can only be another historical illustration of the dangers besetting those who turn to anthropology for evidence to establish a theory.

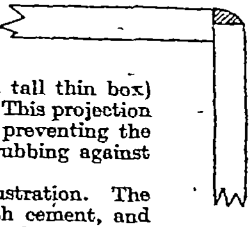
Maudsley Hospital, London, S.E.5. POW-MENG YAP.

PERSPEX SPECIMEN BOXES

SIR,—For museum specimens I have used 'Perspex' containers for a year, and have seen no sign of deterioration. I am glad, however, to see Mr. Fatti's favourable report (Feb. 1) after two years' experience with boxes made by Mr. John Carr.

Apart from a pleasing appearance, the special attractions of these containers are (1) that they are "made to measure," thus saving size and weight, and obviating the need for a large stock of jars of all sizes and shapes; and (2) that, unlike some glass jars, they withstand changes in atmospheric temperature and pressure without leaking or cracking. My technique, which is rather different from Mr. Carr's, is designed for people with little equipment or skill in carpentry.

The four upright sides are cut from $^{1}/_{8}$-in. sheeting and cemented with perspex cement no. 6 on to a base cut from $^{1}/_{4}$-in. sheeting. The base is cut large enough to project about $^{1}/_{4}$ in. beyond each of the four vertical panels or (in the case of a tall thin box) sufficiently for it to stand firmly. This projection reduces the risk of scratching, by preventing the sides of one box from knocking or rubbing against those of another.



The sides are joined as in the illustration. The trough on the outside is filled with cement, and as this shrinks with drying it must be filled several times. Next day the joint is smoothed and rounded with a file, after which the polish can be restored by coating the filed surface with a thin layer of cement. With this type of joint accurate carpentry, though desirable, is not essential; quite large gaps can be invisibly filled. It is best, before cementing, to file any cut edges, so as to remove saw marks, which might trap air-bubbles; but there is no need to apply pressure to the joints. The box is tested for leaks by filling it with water.

The specimen is sewn to a sheet of $^{1}/_{16}$-in. perspex through holes pierced with a hot needle. It is then placed in the box (previously filled with mounting fluid so that no unnecessary strain is placed on the supporting stitches) and the box is filled to within $^{1}/_{2}$ in. of the top. There is no need for supporting struts.

A piece of $^{1}/_{8}$-in. sheeting is laid on the top of the box, and the pattern for the lid is marked on the under surface by running a pencil around; the saw cuts are made slightly inside the pencil marks. The lid is now cemented on with a joint like those at the sides, the trough being filled with cement in the same way. Finally, the box is completely filled with mounting fluid, in which the appropriate amount of sodium hydrosulphite for colour restoration has been dissolved, through a small hole pierced in the lid. The hole is sealed with a blob of cement, and the joint holding the lid is rounded and polished in the same way as the side joints.

JOINT CHANGES IN CANCER OF THE LUNG

SIR,—Your annotation of March 22 almost coincided with a report by me to the section of medicine of the Royal Society of Medicine of 3 cases of gross pulmonary osteoarthropathy with lung cancer, which have come under my care during the past three years. In these cases the lung tumours were practically symptomless, and the connexion between the joint and lung conditions was not immediately apparent. In all, however, chest radiology in the anteroposterior and lateral planes revealed a tumour, while additional investigations revealed the precise nature of the lung lesion. All 3 cases were referred to me as examples of atypical rheumatoid arthritis.

CASE 1.—This was a man of 55 whom I saw at the Rheumatism Unit of the London County Council on account of pain, swelling, and stiffness of both knees, thickening of the long bones, and marked crippling. Examination revealed a rheumatoid type of lesion with effusions into both knee-joints. Examination of the synovial fluid showed a cytology typical of a non-specific rheumatoid lesion. The condition was complicated by gross pulmonary osteoarthropathy with an ossifying periostitis of the radius, ulna, femora, tibiæ, and fibulæ. *The fingers, toes, and even the nose* showed gross clubbing. There were no symptoms referable to the chest, but investigation showed a well-defined opacity in the right upper lobe. Mr. R. C. Brock, who kindly saw the patient for me, decided that his condition would only permit a lobectomy. Subsequent histological investigations showed the growth to be a bronchial carcinoma. Almost immediately after its removal the knee-joint swellings began to subside, and the fingers, toes, and nose became less clubbed; now, nearly two years later, the joint and soft-tissue swellings have almost completely subsided.

CASE 2.—A man, aged 48, had similar physical signs and was likewise operated on by Mr. Brock. Secondary mediastinal-gland involvement was treated with deep X-ray therapy, which unfortunately flared up a latent tuberculous focus that was not revealed clinically or radiologically; and he succumbed to this.

CASE 3.—This patient, a man aged 53, is at present under investigation. I first saw him a month ago as a case of "polyarthritis." The history was of rather sudden onset of pain, swelling, and stiffness of the knees some twelve months previously, followed within a month by swellings of the ankles, fingers, and toes. The swellings subsided after a month in bed, and the patient resumed work in spite of disablement. Six months later recurring joint swellings increased his crippledom, and three months ago he was obliged to give up his work. When I saw him he presented a clinical picture of a somewhat acute rheumatoid arthritis; he was febrile (99–100° F); there was pronounced anæmia, with lymphadenopathy but no clinical enlargement of the spleen. The joint changes included effusions into both knees and some involvement of the wrists, left elbow, left shoulder, and ankles; *and the condition was complicated by gross clubbing* of the fingers and toes and thickening of the long bones. Clinical examination of the chest showed no localising physical signs. The knee-joint fluid was typical of a non-specific rheumatoid lesion. X-ray examination of the chest showed in the lateral view a well-defined rounded opacity, 2½ in. in diameter, lying in the posterior basal segment of the right lower lobe. Although bronchoscopy has revealed little abnormal the findings favour a peripheral carcinoma of the lung. Mr. Brock will be seeing the case for me with a view to thoracotomy and possibly pneumonectomy.

In neither of the first 2 cases was there any real evidence of extensive tissue breakdown or appreciable infection; *and the association of the joint* and lung conditions on the basis of infection alone or of anoxia (suggested as possible causes) is difficult to explain.

The potential significance of the pituitary in relation to the ætiology of chronic arthritis has received some attention in recent years, and the connexion between acromegaly and pulmonary osteoarthropathy has been noted by Fried[1] in his work *on lung cancer*. *He has* advanced the theory that the diffuse pulmonary osteoarthropathy found in some cases is probably due to a dyspituitarism akin to acromegaly. The possible relation of endocrine imbalance to chronic arthritis and pulmonary osteoarthropathy in these cases is significant, the pathogenesis of diffuse pulmonary osteoarthro (Bamberger-Marie's disease) is as obscure today as it was first described by Bamberger and Pierre Marie 1889 and 1890 respectively. Can one postulate, Crump[2] has done, an abnormal substance circu in the blood, affecting the periosteum, the bones, joints, and the soft parts of the terminal phalanges evidenced by clubbing of the fingers? And might the lungs—"pulmonary glands," as Aschoff[3] others has suggested—take on additional functions secretory organs? Certainly the association of join changes, osteoarthropathy, and lung-cancer is wort of more detailed investigation.

London, W.1. PHILIP ELLMAN.

HEALTH INSURANCE IN THE UNITED STA

SIR,—The commercial insurance interests of A are seeing to it that the proposed Federal health insurance scheme, backed by President Truman, does not become law—not if they can help it. Here is a sample of one their widely circulated leaflets, headed *Socialised Medicine —Bad Medicine for You!*

Dr. Edward H. Ochsner of Chicago testified at the recent Wagner-Murray Bill hearings in Washington that

This is how it was in Britain:

The doctor got back to his office just at 2 o'clock. "How many?" he said to his nurse. "Forty." Casually, without hurry, he put on his white jacket and poked his head into the waiting-room where the forty patients sat: "Will those of you with headache please stand?" he said. Six stood. The doctor took identical printed prescriptions out of his desk and handed one to each of the six and dismissed them. "Will those of you troubled with a cough please stand?" Another group got up and again he handed them printed prescriptions and dismissed them. The others he took one by one into his private office for a few minutes. Two hours later the office was empty, the 40 patients gone, an average of 3 minutes per patient. In Germany, under compulsory insurance, some doctors did even better—30 to 40 patients in one hour!

This same leaflet lectures insurance managers to be more active on the political war-path.

"It is, of course, not natural for executives whose job it is to smell a dollar to delve into this field, because there can't be a profit—the objective being merely to avoid losing money. But it is a matter of large import to private insurance from the long-range standpoint. We need only recall that England has had a cash sickness scheme since 1911 and now industrial life insurance and workmen's compensation have become lost to commercial insurers!"

Shiplake. RONALD DAVISON.

SUCCESSFUL REVACCINATION

SIR,—I frequently dispute two widely held inferences about revaccination: that an early reaction is evidence of immunity, and that "no reaction" is unacceptable because it is due to failure to vaccinate properly. I welcome Dr. Broom's paper (March 22) as supporting my views.

For revaccination to be properly performed and recorded there are four essentials: the lymph must be potent; the technique must be correct; the reading of the reactions must be accurate; and the interpretations of the findings must be true. I maintain that today it is possible for every one of these factors to be at fault and yet for the subject to be certified as successfully vaccinated. Paradoxically it is the desire to eliminate such faults, by refusing to accept a "no reaction," which has been largely responsible for recent reports *of a high incidence* of smallpox among the recently vaccinated.

It is but a short step from the standpoint that "there must be some reaction to vaccination" to the erroneous and dangerous assumption that any sort of reaction is evidence of successful vaccination and no reaction is proof of failure. It is precisely among those early reactions which are called "reactions of immunity" that the most serious errors of interpretation are made.

The explanation of my views will be helped if the term "immunity" is avoided and the subject is considered in terms of susceptibility. Vaccination is both a test of susceptibility and an immunising inoculation. The highly susceptible respond by a typical *primary vaccinia*; the less susceptible show a so-called accelerated reaction, which is better described as an *abortive vaccinia* or *vaccinoid*; while the insusceptible show *no visible response at all*, as in 238 of Dr. Broom's 1227 cases.

---

[1] Fried, B. M. *Arch. intern. Med.* 1943, 72, 565.

[2] Crump, C. *Virchows Arch.* 1929, 271, 467.

[3] Aschoff, L. *Z. ges. exp. Med.* 1926, 50, 52.

Besides these responses others may appear which are not concerned directly with susceptibility; of these, the most important is the sensitivity reaction to products of the virus, living or dead. The reaction develops in some of those who have had previous experience of vaccine lymph. It may occur in all the above groups—the highly susceptible, the less susceptible, and the insusceptible—although it is true that there is some association between sensitivity and immunity, because sensitivity implies previous exposure to the virus and an opportunity of acquiring resistance. Now, Sir, despite a vast literature on immunology and allergy, the distinction between immunity and sensitivity is still confused; and frequently reactions of sensitivity are accepted as evidence of immunity. In vaccination this is particularly dangerous, because vaccination requires the use of a living virus and the sensitivity response can occur with inactive lymph, as the 110 control reactions in Dr. Broom's series show.

It comes to this: if revaccination is followed by primary vaccinia or aborted vaccinia, the subject is susceptible and the vaccination has boosted his resistance to a safe level. (It would help enormously if we restricted the term "*successful vaccination*" *to the susceptible* and held that the immune cannot be successfully vaccinated.) If revaccination is followed by an early reaction or by no reaction, no positive inference can be drawn as to the susceptibility of the individual. The early reaction may be specific, non-specific, or traumatic. If specific, it may be a sensitivity response to the products of the virus, living or dead. What is certain is that it is not a reaction of immunity, and this term should be dropped. On the other hand, if no reaction occurs the vaccination may be faulty in some way or the subject may be immune. In face of this uncertainty repeated revaccination may be desirable, but no further inferences can be drawn beyond those stated above. For these reasons I agree with Dr. Broom in advocating a change in the international certificate of vaccination.

INFANTILE INSOMNIA AND MATERNAL GRAVES'S DISEASE

SIR,—The following case-histories show that infantile insomnia may be the presenting symptom of maternal Graves's disease, and they are also interesting as a study in the emotional relationship between mother and child.

Mrs. A came to the outpatient department with her first child, aged 5 months. Her complaint was that the baby never slept for more than an hour or two consecutively. The baby proved to be a fine healthy if over-active bottle-fed girl, weighing 14 lb. 12 oz. and looking the picture of health. Her mother, however, said that she herself had lost 10 lb. in weight since the birth of her child. The mother was found to have tachycardia, with a pulse-rate of 100 per min. at rest, slight exophthalmos, a visible swelling of the thyroid, and a fine tremor of her fingers.

Mrs. B, the mother of two boys, separated from her husband for the past year because he had to work in Wales while the home remained in London, brought her son, aged 2 years, with the complaint that he was very restless at night, sleeping a total of 4 hours only. With him came his brother, aged 4 years. They were tough noisy healthy children, over whom their mother had little control. She looked worn out, had well-marked exophthalmos of some years' standing, a pulse-rate of 110 per min. at rest, tremor of the fingers and hands, a palpable swelling of her thyroid, and obvious over-anxiety.

Mrs. C, an excitable Jewish mother, brought her first child, aged 9 months, with the complaint that the baby girl apparently never slept either day or night. She was a large lackadaisical over-fed child, constipated but otherwise healthy, weighing over 20 lb. She was in the process of being weaned and had a good mixed diet in addition to four breast feeds daily. The mother was stout, florid, and emotional. She thought she had lost weight herself, but did not know how much. She had a very variable pulse-rate which was consistently over 100 per min. at rest. Her exophthalmos was not pronounced, but she had a lid-lag and a fine tremor of her fingers. She said her nerves had been bad since she had tried to wean the baby at 6 months and had failed.

All these children slept within earshot of their mothers, the two girls in the same room and the boy in the next room with an open communicating door. In the first two histories there was no question of the babies getting too much thyroxine from their mothers' breast milk, and, although this is a possibility in the last instance, the appearance of positive health with a regular gain in weight in all these infants belied their mothers' stories of insomnia.

It seems probable that they were normal healthy babies whose every cry or movement was heard by an over-anxious parent, and whose insomnia if not entirely imagined was induced by their mothers, who picked them up and generally disturbed them every time they so much as whimpered or turned in their sleep.

All three patients came to the outpatient department of the Hospital for Sick Children, Great Ormond Street, within a year. The mothers had to be sent elsewhere for confirmation of the diagnosis and treatment. This confirmation was obtained from the adult hospital in each case. No treatment was given to the children, two of whom are reported, in reply to a written query, to be sleeping well, while their mothers, who are at home, say they themselves are much improved. These two mothers are being treated with thiouracil; the other one has not yet left hospital.

I wish to thank the honorary staff of the Hospital for Sick Children for permission to publish these case-histories.

R. E. BONHAM CARTER.

Great Ormond Street.

THIOCYANATE FOR HYPERTENSION

SIR,—In his article of March 15 Dr. Mills claims that potassium thiocyanate produced striking symptomatic relief in 27 cases of benign hypertension in which headache and dizziness were prominent symptoms. He states, however, that the drug does not permanently lower the blood-pressure, even in cases in which there is much symptomatic relief. These results are at variance with those of other workers published in the past ten years. They have claimed to produce relief of symptoms in a much smaller proportion of cases, but have often found a reduction of blood-pressure. A typical example is the report of Barker et al.[1] on a carefully controlled series of 246 hypertensives treated with thiocyanate for 2–11 years. Persistent symptomatic improvement occurred in 56%, and reduction of blood-pressure by 30/20 mm. or more was obtained in 67%.

Dr. Mills's failure to lower the blood-pressure was probably due to inadequate dosage. He aimed at a blood thiocyanate of 5–8 mg. per 100 ml., whereas previous writers have found 8–12 mg. necessary. One wonders whether the doses Dr. Mills used could have had much real effect on the patients. In considering the claims of any treatment to relieve the symptoms of hypertension without lowering the blood-pressure, the work of Ayman[2] should be borne in mind. He produced decided symptomatic relief in 82% of a series of hypertensives by administering solemnly and with enthusiasm doses of coloured water.

S. G. SIDDLE.

SIR,—Dr. Geoffrey Evans has asked me to correct a mistake in my paper in your issue of March 15. I stated that in his paper with Dr. D'Silva he maintained "that some benefit was derived from this drug in all cases." Apparently I had not made my meaning clear. I wished to point out that although they likewise found that headache was the symptom which was most relieved by potassium thiocyanate, they also found that all symptoms obtained some benefit in certain cases—for example, insomnia and mental changes (lack of concentration). I was unable to confirm any benefit in cases with such

COMPRESSION OF MEDIAN NERVE IN CARPAL TUNNEL

SIR,—Since our article appeared on March 8 we have seen a paper by W. B. Cannon and G. J. Love in *Surgery* (1946, 20, 210) reporting 9 patients in whom the transverse carpal ligament was divided for median compression. In 3 cases the condition was thought to have arisen spontaneously, and the characteristic swelling of the nerve is described.

STEVENS-JOHNSON SYNDROME

SIR,—I was most interested in the accounts by Dr. Maurice Nellen and Dr. J. O. Murray in your issue of March 15. It is strange that so few reports of the syndrome have appeared in England, for there are many references to it in Continental and American literature. A case was described, however, by Low and Davies[1] in 1938, under the diagnosis of dermatostomatitis—the name given to the condition by Baader in 1925.

It is not very uncommon here; in the last six years I have seen 8 identical cases, which will be reported in detail elsewhere. Of these, 5 were in young male adults in the Royal Navy, while 3, seen during the last six months, were civilians. The later group included one woman of 55 and a child of 9, the onset of whose illness followed a trivial injury to the lip, as in Dr. Murray's first case.

It is impossible not to be struck by the constancy of the symptoms and of the course of the illness; it does appear to me to be an entity and not a variety of erythema multiforme. This conclusion is also reached by the *Commission on Acute Respiratory Diseases*, of Fort Bragg, N.C., in a recent article on the association of the syndrome with atypical pneumonia.[2] Despite extensive bacteriological and animal inoculation studies, they were unable to establish the ætiology.

The impression from American articles that severe ocular complications are common has not been borne out in the cases I have seen; only 1 of my series developed chronic conjunctivitis, and the remainder recovered completely.

THE TRAINING OF FUTURE PSYCHIATRISTS

SIR,—Admitting my temerity, I submit that the recommendations for the future training of D.P.M. candidates set out in the interim report of the committee on psychological medicine of the Royal College of Physicians, and embodied to some extent in the new Conjoint regulations for this diploma, are uninspiring, and that if followed they will tend to produce psychiatrists who are robots. Not very good robots either, because the recommendations contain serious sins of omission as well as of commission.

To train in a circumscribed subject for five years with the object of taking an examination at the end of that time is a formidable task. The temptation to "learn" current official viewpoints and not to develop gradually individual thought will be a pitfall difficult to avoid. The first five years of a would-be psychiatrist's life are highly impressionable. That his goal at the end of that journey should be the passing of an examination does not seem the most sound way of developing the best that is in him. A good examinee and yes-man would be the safest albeit the least desirable candidate.

A less imposing qualification than the proposed future D.P.M., and an honours qualification that could be acquired later, or recognised useful stages of the D.P.M., to be passed at intervals of six months to a year, would be much sounder propositions.

That the value of a certain period of non-medical work in the training of a psychiatrist is not recognised or recommended as part of the D.P.M. curriculum is a great pity. The average medical man or woman, this includes psychiatrists, has actually rubbed sho on equal terms very little with the workaday, un cally minded world. The journey has been from c to university, thence to the medical school and w with very little time to spare for other than nec recreation. Three to six months' compulsory work outside medical and psychiatrically trained circles wo be a valuable part of training and in many might be the starting-point of original psychiatr thought.

The omissions in the recommendations are dep That a personal analysis should be considered a n part of the training of a psychiatrist is surely as re as to expect that the student of medical anatomy sho spend some time in the dissecting-room. There are *things, in fact the most important things, in psyc* that cannot be learnt from a book or by attending lec and clinics. Only the physician who has faced the in his own mind will be able to search fearlessly the of his patient. And just as it is important to main strict asepsis in the operating-theatre, so it is ne that the psychiatrist should not project his own pro into the therapeutic session. This danger can only guarded against by the deeper self-knowledge acq during personal analysis.

I feel that the recommendations for the training future psychiatrists ignore the intelligence and la abilities of the men and women who wish to take this fundamentally important branch of medicine, that if carried out they will seriously hinder the deve ment of British psychiatry.

Cassel Hospital, Stoke-on-Trent.
